The story of the Martian samples on Earth will then begin under the constraints recommended by the Planetary Protection Panel of COSPAR and other dedicated scientific and institutional bodies.

Planetary Protection and Contamination Control Issues

The MSR mission is facing numerous challenges in ► [planetary protection](#) (PP): (1) for protecting Mars from the possible development of viable Earth organisms; (2) for protecting Earth from potentially bio-hazardous Martian material; and (3) for preventing false-positive identification of material thought to be Mars organisms in the returned samples (but actually originating from Earth), which will affect seriously the science and PP policy in the future.

The last challenge needs to control organic and inorganic contaminants in the returned sample, in some cases to levels as low as the part-per-billion range. Both science and PP require sterilization and/or thorough cleaning of any hardware that

comes in contact with the samples and subsequent isolation from dirtier parts of the spacecraft to avoid recontamination. Both also benefit from inventory of materials and organisms on the spacecrafts before leaving Earth as an additional mean of preventing false-positives for life detection and ambiguity in science observations.

Preventing contamination of Mars by Earth organisms associated with landed spacecraft requires reduction of the ► [bioburden](#) on surface materials by cleaning, and containment or ► [sterilization](#) of internal materials. Elements expected to crash on the surface (the lander cruise, entry, and descent systems) must further reduce the bio-loads of internal hardware, since containment cannot be assured, and/or demonstrate sufficient sterilization by atmospheric entry heating.

Preventing contamination of Earth by potentially bio-hazardous Martian material requires highly reliable sample containment and ultra-safe entry and landing at Earth, as well as breaking the chain-of-contact with Mars in a way that precludes release of Mars organisms outside of sample containment.

Mars Sample Return Mission, Fig. 2 December 28, 2021, the rover Perseverance filled already 6 RSTAs. Before the coring the drill abrade few millimeters of the surface in the close vicinity of the place to be drilled and a photo taken by the camera WATSON (ABRADE). Then

after the coring a photo of the visible surface of the sample is taken by the camera CacheCam before the closure of the tube (CORE#) including the name of the sampled place and underlined with the mission sol number of the sampling. (Credit: NASA/JPL-Caltech/ASU/MSSS)

Future Directions

MSR began, actually, with the launch of Perseverance. The dream of planetologists and astrobiologists is now a perspective. Analysis is still ongoing to optimize the mission. For instance, based on the heritage of the precise landing of former NASA rovers, the MAV and SFR could be launched separately. On Earth international committees and institutions organize the arrival of the samples and prepare the plans to identify the samples, store as pristine samples a significant portion for the future generations, split the remaining portion either for life detection or bio-hazard testing under quarantine conditions and a portion for subsequent analysis in regular laboratories after the quarantine or sterilization.

The participating and associate organizations are developing consequent efforts of R&T to

welcome, store, and analyze those precious samples in the respective receiving and curation facilities in the USA and in Europe.

Definition

Mars Science Laboratory (MSL) is a NASA mission that delivered a rover to Mars designed to

quantitatively assess past and present habitable environments within the rover’s field area. The mission’s habitability investigation is part of the overall strategy of NASA’s Mars Exploration Program to understand whether life ever was present. After a decade of development, the mission launched on November 26, 2011, and the Curiosity rover touched down at Gale crater on August 6, 2012.

Overview

The MSL Curiosity rover (Fig. 1) was designed to be a virtual field geologist and mobile geochemical laboratory with objectives of deciphering geological history and processes, exploring major climate transitions recorded in the rock record, determining the chemical and mineralogical compositions of surface materials, including an inventory of organic molecules, assessing energy sources that could sustain biological processes, and identifying the subset of habitable environments also capable of preserving organic molecules. Additional objectives include characterizing the modern meteorological and radiation environment, and measuring the stable isotopic and noble gas compositions of the present-day atmosphere and of volatiles released from solid samples.

These science objectives are accomplished using a payload (Grotzinger et al. 2012) consisting of science cameras and a laser-induced breakdown spectrometer mounted on the rover’s mast; a camera and alpha-particle X-ray spectrometer mounted on the rover’s arm; an X-ray diffractometer and mass spectrometer, gas chromatograph, and tunable laser spectrometer suite carried within the rover chassis, an active neutron spectrometer, meteorology station, high-energy radiation detector, and descent/surface imager. Solid samples are scooped or drilled from the surface, processed, and delivered to the onboard laboratories using a sampling system on the rover’s arm (Anderson et al. 2012). A radioisotope power system and batteries provide energy.

Gale crater was selected as Curiosity’s field area because orbiter-based investigations suggested that the crater’s plains and central mound

Part of this research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration (80NM0018D0004).

M

taken by rover’s arm-mounted camera. (Image credit: NASA/JPL-Caltech/MSSS)

(Fig. 2) hold a diverse record of potentially habitable environments dating from the early Hesperian (Grotzinger et al. 2012; Golombek et al. 2012). The layered central mound (Aeolis Mons, or informally Mount Sharp) was interpreted as flat-lying sedimentary rock with textural and mineralogical attributes that vary with relative age, including phyllosilicate and hydrated sulfate-bearing strata that suggest aqueous interaction (Milliken et al. 2010). Plains northwest of the mound (Aeolis Palus) offered a safe landing area with alluvial fan and other stratified deposits.

Exploration of hundreds of vertical meters of stratigraphy (Fig. 3) has revealed a succession of stream, delta, and lake depositional environments representing millions, perhaps tens of millions, of years (Grotzinger et al. 2015). Subsurface fluids

interacted with the sediments in multiple episodes after deposition, texturally and compositionally overprinting the rocks (Nachon et al. 2014; Krontyak et al. 2018; Sun et al. 2019; Achilles et al. 2020). Mast- and arm-based observations, as well as the analysis of dozens of drilled samples, show Aeolis Palus and Aeolis Mons to consist of dominantly clastic sedimentary rock composed of basaltic igneous minerals, secondary phases including hydrated phases, and X-ray amorphous materials (Rampe et al. 2020). Curiosity’s chemical and mineralogical results are consistent with surface and subsurface environments that remained within the ranges of temperature, pH, and salinity that could have supported life over much of the time that fluids were present (Grotzinger et al. 2014). A diversity

Mars Science Laboratory, Fig. 2 Panorama of Aeolis Mons (Mount Sharp) showing dark capping rocks (a) below active dark sands of the Bagnold dune field (b). Above the dune is a series of strata that include lacustrine

mudstones (c), additional planar capping units (d), rounded hills with evidence of sulfate minerals from orbiter data (e), and bright, anhydrous units (f) that form the top of the mountain. (Image credit: NASA/JPL-Caltech/MSSS)

Mars Science Laboratory, Fig. 3 Rendering of lower Aeolis Mons showing the rover's traverse path from 2017 onward, along with major geological and mineralogical units. As of July 2021, the rover has reached the transition

between the clay- and sulfate-bearing units. (Image credit: NASA/JPL-Caltech/ESA/University of Arizona/JHUAPL/MSSS/USGS Astrogeology Science Centers)

of organic molecules has been detected (<300 ppb; detections up to C₁₂ with evidence of higher molecular weights) in clay-bearing mudstones, in spite of the rocks' age and exposure to radiation (Freissinet et al. 2015; Eigenbrode et al. 2018). Igneous clasts and the mineralogy of some sedimentary samples argue for unexpectedly high magmatic diversity around Gale crater (Sautter et al. 2015; Treiman et al. 2016).

Curiosity has observed active sand transport in ripples, sand sheets, and dunes (Bridges and Ehlmann 2018; Lapotre and Rampe 2018). Analyses of atmospheric samples and water released from clay minerals indicate the preferential loss of light isotopes, consistent with atmospheric escape (Webster et al. 2013; Mahaffy et al. 2015). Atmospheric methane is found to vary diurnally and seasonally, indicating active production, likely from subsurface seepage (Webster et al. 2021). Meteorological observations over multiple Mars years have revealed the influence of the crater on wind, pressure, and atmospheric dust (Rafkin et al. 2016). Water ice clouds and hazes increase during the aphelion season, preceded by the appearance of noctilucent and iridescent high-altitude clouds. Curiosity had a unique surface vantage point for its measurements during the 2018 planet-encircling dust event (Guzewich et al. 2019). Measurements of high-energy radiation show the shielding effects of the atmosphere and topography, providing key inputs to radiation transport codes and constraints for future crewed exploration of Mars (Guo et al. 2021).

Mars Stratigraphy

Ernst Hauber
Deutsches Zentrum für Luft- und Raumfahrt
(DLR) e.V., Institut für Planetenforschung,
Berlin, Germany

Keywords

Chronology · Sedimentary rocks

Definition

Stratigraphy, from Latin *stratum* (layer) and Greek *γραφειν* (to write, describe), is the description of all ► **rock** bodies forming the Earth's (or any rocky planetary body's) ► **crust** and their organization into distinctive, useful, mappable units based on their inherent properties or attributes, in order to establish their distribution and relationship in space and their succession in time, and to interpret geologic history (definition by the International Commission on Stratigraphy ICS, a scientific body within the International Union of Geological Sciences, IUGS). In a broader sense, stratigraphy is often equated with relative and absolute age determination.

Overview

The stratigraphic scheme for ► **Mars** was first outlined from photogeologic mapping of Mariner 9 data (Scott and Carr 1978) and was later refined on the basis of ► **Viking** orbiter image analysis (Tanaka 1986). It divides the history of Mars into three systems (of time-stratigraphic units) or periods (the chronologic equivalents of systems): ► **Noachian**, ► **Hesperian**, ► **Amazonian** (from lowest to highest or oldest to youngest), which are further subdivided into eight series or epochs. The Noachian System is subdivided into the Lower, Middle, and Upper Noachian Series, and the Noachian Period is subdivided into the Early, Middle, and Late Noachian Epochs, respectively. Similarly, the Hesperian is subdivided into the Lower and Upper Hesperian Series, or the Early and Late Hesperian Epochs. The Amazonian is subdivided into the Lower, Middle, and Upper Amazonian Series, or the Early, Middle, and Late Amazonian Epochs. Absolute model ages of the periods and epochs were determined on the basis of crater counting (Tanaka and Hartmann 2008; Michael 2013). Recent high-resolution images allow the establishment of detailed (but local) stratigraphic columns and mapping approaches similar to techniques used in sequence stratigraphy on Earth (Pondrelli et al. 2008).

Mars, Delta

Barbara De Toffoli
German Aerospace Center, DLR, Berlin,
Germany

Keywords

Water availability · Sediment deposition · Habitability

Synonyms

[Delta deposit](#); [Delta fan](#); [Fluvial or river delta](#)

Definition

River deltas are landforms generated by deposition of fluid-carried sediments as the flow enters a slower-moving or stagnant water body. Deltas appear as fan-shaped and flat-topped deposits fed by a channel, but they may display diverse morphologies due to several factors including climate, geology, and drainage system characteristics. Well over a hundred deltas are present on Mars, mainly located close to the dichotomy boundary. These features can be indicators of past water availability and are favorable sedimentary settings for organic matter preservation. Accordingly, the Jezero crater delta has been targeted as a landing site for the Perseverance rover mission in 2021.

Overview

River deltas are landforms generated by deposition of the sediments carried by the river water as the flow enters a slower-moving or stagnant water body. When the flow enters the standing water, it is no longer con-fined to its channel and expands in width. This flow expansion results in a decrease in the flow velocity, which diminishes the ability of the flow to transport sediment. Deltas may display diverse morphologies due to several factors including climate, geology, river characteristics, basin bathymetry, and waves and tide regimes. The presence of ancient delta deposits on Mars has been thoroughly demonstrated for decades (Di Achille and Hynek 2010; Ori et al. 2000; Di Biase et al. 2013). Delta fans usually appear as fan-shaped deposits fed by a channel, characterized by either a stack of steep foresets (i.e., the sloping surface developing from the delta front due to progressive sediment deposition) of decreasing radius, or by a single steep foreset, either flat-topped or branched (De Villiers et al. 2009, 2013; Hauber et al. 2013). Deltas are distinguished from alluvial fans which differently appear gently sloping semiconical landforms associated with the discharge of water and sediments from a confined channel into an unconfined terrain characterized by the absence of a standing body of water (e.g., Moore and Howard

2005). As of today, around a hundred and sixty deltas have been identified on the Martian surface distributed on a large elevation range. Many deltas can be found in proximity of the dichotomy boundary (i.e., the boundary between the southern and the northern hemisphere of Mars characterized by a sharp elevation contrast that can be followed on a global scale), and a vast majority are located into craters or topographical depressions that could have acted as ponds/lake at the moment of the delta generation (De Toffoli et al. 2021; Wilson et al. 2021; Rivera-Hernández and Palucis 2019). Delta deposits are geological features highly relevant for astrobiology and the search for life and biosignatures on Mars due to their potential as indicators of past water availability, habitable environments, and as favorable sedimentary settings for organic matter preservation (Summons et al. 2010). In February 2021, the Perseverance rover landed in Jezero crater where an ancient river delta was detected from orbital images (e.g., Goudge et al. 2017; Mangold et al. 2020). The mission outcomes confirmed the deltaic nature of the geological formation and identified the hydrologic regime in place during sediment depositions, suggesting both a prolonged lake environment and later highly energetic paroxysmal fluvial flows (Mangold et al. 2021).

Mars, Erosion Rate

Giulia Alemanno

Institute of Planetary Research, German
Aerospace Center, Berlin, Germany

Definition

The geomorphology of a terrestrial planetary surface is characterized by erosional and depositional features. These features are produced by weathering and erosional processes. The erosion rate is the measure of the loss of soil mass over a specific time period. The study of the erosion rate of a planetary surface is a key to investigate the climatic conditions that have acted on that surface and to study its climatic evolution through time. The modification of the Martian landscape throughout erosional and depositional processes has been studied by several authors (e.g., Golombek and Bridges 2000; Kleinhans 2005; Golombek et al. 2006; Vigier et al. 2006). Estimation of erosion rates of Martian fluvial structures has been performed to study the history of water on Mars and in turn to estimate his paleo-climatic history (e.g., Hoke and Jordan 2010; Orofino et al. 2018).

Definition

Hydrated minerals are minerals that contain water or hydroxyl (OH) in their structures. They are the result of alteration and weathering processes due to surface liquid water and/or hydrothermal activities.

Overview

Hydrated minerals provide key information on Mars' past climate, climate change phase(s), and potential for habitability. Their widespread presence on the surface of Mars is an indicator of

water-bedrock interaction in a geologically long period of time. Some hydrated minerals contain bound H₂O in their structure, and others require OH. Some others can absorb water molecules and keep it in their structure. Therefore, hydrated minerals on Mars offer a wealth of information on the surface water inventory at the time of their formation and on the chemical and physical conditions of their surrounding area. The main group of hydrated minerals detected so far on Mars include phyllosilicates (e.g., kaolinite, smectite), sulfates (e.g., jarosite, kieserite, gypsum), carbonates (e.g., monohydrocalcite, artinite, hydromagnesite), ferric hydroxides (e.g., goethite, akaganéite, ferrihydrite), and other hydrated minerals (e.g., zeolite, opal). Carbonates may form in both anhydrous and hydrated conditions.

Hydrated minerals on Mars have already been detected in the spectroscopic data from Earth-based observations and early orbital instruments. Hydrated minerals such as carbonates, sulfates, phyllosilicates, and iron oxides have also been detected in Martian meteorites. More recent data (imagery and spectroscopic) from various orbiters, landers and rovers reveal a past history of liquid water activities on the Martian surface. Data from Pathfinder's Alpha Proton X-Ray Spectrometer (APXS) shows the presence of excess oxygen in form of OH or water bound in minerals. The Mars Exploration Rover (MER) Opportunity data indicates the presence of hydrated sulfates in Terra Meridiani. In Gale Crater, Mars Science Laboratory (MSL) rover data point to the presence of Gypsum (Ca-sulfate) as light-toned material filling veins in Yellowknife Bay. The Mars Express Observatoire pour la Minéralogie, l'Eau, les Glaces et l'Activité (OMEGA) infrared spectrometer and Mars Reconnaissance Orbiter's Compact Reconnaissance Imaging Spectrometer for Mars (CRISM) hyperspectral instrument have provided an extensive knowledge about the Martian surface mineralogy and the widespread distribution of various hydrated minerals. The global data shows that Mars's surface has underwent diverse and complex aqueous settings from clay-forming environments to the precipitation of evaporite minerals and to the presence of chloride and perchloride salt detected at the landers and

rovers landing site. These aqueous settings include standing bodies of water in impact craters, valley networks, outflow channels, ice-covered lakes, desiccating ponds, brines, seasonal ice/snow melt, and appearance of microscopic cryobrine on the current surface. Although hydrated minerals point clearly to a different climate during early history of the planet, it is yet unclear whether the early Mars climate was "warm and wet" or "cold and icy" with episodic warm phases. Further investigation on Early Mars mineralogy, and particularly on hydrated minerals, may hold the key to the question of Early Mars climatic conditions.

[Oceanus Borealis](#)

Definition

The word “ocean” derives from the Greek “okeanos” designating the great body of water that, at the time of the ancient Greeks, was believed to surround the entire landmass of the then-known world. The term subsequently came to designate the continuous body of salt water that covers approximately 71% of the surface of the planet, surrounding all the continents and containing about 97% of its surface water, while also acting as the critical reservoir for maintaining Earth’s global hydrological cycle. Where land encloses a body of surface water, smaller than an ocean, this is best termed a “sea.”

History

The idea of surface-water bodies on Mars has a very long history in human thought. However, it was not until the availability in the early 1970s of

orbital spacecraft imagery from the Mariner 9 Mission that attention became focused on the scientific significance of a great planetary dichotomy, separating heavily cratered southern and equatorial highlands from extensive northern lowlands, known as the Vastitas Borealis. By the mid-1980s, geological study of the relatively high-resolution Viking spacecraft imagery stimulated several scientific investigators to hypothesize that ancient inundations of water or mud had temporarily occupied the northern lowlands. An important observation was that of continuously traceable contacts involving topographic and/or albedo contrasts, interpreted by Parker et al. (1989, 1993) as being the shorelines of ancient seas that had formed within the Vastitas Borealis. It subsequently became clear that these seas could have constituted an Oceanus Borealis on ancient Mars that would have been a critical component for a global hydrological cycle (Baker et al. 1991), and that this paleohydrological cycle could explain the many other water-related geological features that were being discovered (Baker 1982, 2001). There followed a long period of controversy and discovery related to Oceanus Borealis, its geological history, and the implications of its presence or absence for the evolution of the planet.

Overview

Oceanus Borealis consisted of seas that, prior to about 3 billion years ago, episodically occupied Vastitas Borealis. It had at least two major phases and/or levels: Deuteronilus and Arabia (Parker and Bills 2021). Moreover, there is evidence, much degraded, for even older, higher-level seas.

The Deuteronilus phase is dated to the Hesperian time period, approximately 3.5 billion years ago. Its sea level near the Acidalia Planitia region of the northern plains is clearly expressed at about 3900 m below the mean planetary elevation, but it extends to both higher and lower elevations in other regions, mostly varying within a few hundred meters of the 3900-m level. Though the margins of the Deuteronilus Sea mostly lack morphologies indicative of wave-cut shorelines, this

can be explained because of the discovery of tsunami deposits that mantle the shoreline zones and were generated by bolide impacts into the Deuteronilus Sea (Rodriguez et al. 2016).

The Arabia Sea is older, thought to date from the Noachian time period about 4 billion years ago. The Arabia sea level is also several hundred meters higher than the Deuteronilus in the Acidalia Planitia region. However, Arabia sea levels can reach up to few thousand meters higher in other portions of the northern plains. That such immense deviations occur from what should necessarily be a uniform equipotential surface of an ocean would seem to pose a major difficulty for the Oceanus Borealis hypothesis. However, it has been found that true polar wander associated with the growth of Tharsis (Perron et al. 2007) and related tectonic deformations (Citron et al. 2018) can account for these observed deviations from an ancient equipotential surface.

The Deuteronilus Sea developed at a time when immense catastrophic flooding channels developed on Mars. Termed “outflow channels,” these features conveyed huge flows of water (megafloods) to the northern plains from the equatorial highlands, involving sources from either surface impoundments or subsurface aquifers. Sediment-charged megafloods entered the Deuteronilus Sea with such energy that their deposits were spread across the entire northern plains, constituting part of the Vastitas Borealis Formation. The Deuteronilus Sea could have held enough water to comprise a global equivalent layer 110 m deep when spread over the planetary surface (Carr and Head 2019). This value is broadly equivalent to amount of water that subsequently was lost to space, as interpreted from isotopic anomalies in the Martian atmosphere (Villanueva et al. 2015).

The Arabia Sea coincided with the extensive rainfall-induced fluvial dissection of the Martian highlands that produced widespread valley networks (Hynek et al. 2010) and associated crater lakes (Goudge et al. 2015). The valley networks and crater lakes comprise a belt that conforms to the margins of the ancient sea (Chan et al. 2018). Deltas formed along the margins of this belt

(Di Achille and Hynek 2010; Fawdon et al. 2018), and the entire system was subsequently tilted by the development of the Tharsis Bulge (Bouley et al. 2016).

The climatic system associated with Oceanus Borealis has proven difficult to reconcile with theoretical modeling (Turbet and Forget 2019), and this result has provided incentive to pose the hypothesis of a frozen northern plains ocean (Carr and Head 2019). Nevertheless, other model results indicate prevailing warm and wet conditions that are broadly consistent with the geological evidence (Ramirez et al. 2020).

That early Earth had an ocean, the existence of which coincided with the development of life, provides an incentive to pursue further understanding of Oceanus Borealis. This should occur with the 2023 Exo-Mars Mission, which will focus on Oxia Planum, an area situated on a margin of the Arabia Sea.

Definition

The paleoclimate of Mars is the climate of the geological periods prior to the current era in which meteorological parameters such as temperature, atmospheric pressure, and wind speed (and direction) have been measured by the various landers that, since 1976, successfully operated on the surface of the planet. There are various indications that the Martian paleoclimate was very different from the current one, even if, due to the lack of a univocal description of the past conditions of the planet given by the paleoclimatic models, an alternative scenario, almost permanently cold and dry, has been also suggested.

Overview

Introduction

Mars is now a very cold planet with a global average annual temperature of 210 K (−63 °C) (Carr 2006). At the poles, in both hemispheres, mean diurnal temperatures are close to 150 K (−123 °C) (Carr 2006), while during summer in the southern hemisphere, they can reach 300 K (27 °C) (Carr 2006), reaching in exceptional cases up to 310 K (37 °C) (Martin 1991). Temperature falls, however, by 80 °C or more during the night, so that, even on the hottest days, its daily average values are considerably below zero centigrade.

These significant diurnal thermal variations are due to the lack of the balancing action carried out

on the Earth by the oceans and the atmosphere. The latter on Mars is made up almost exclusively of carbon dioxide, is very tenuous and exerts a pressure at the surface of less than 1/100 of that of the Earth. Also the partial pressure of the water vapor is far lower than the terrestrial one. This fact, combined with low temperatures, implies that water cannot exist in a liquid state on the Martian surface, as it solidifies and then sublimates very quickly (except at the poles where ice is relatively stable). Even rain and snow are in fact impossible. The only truly massive atmospheric events on Mars are the great dust storms, some of which affect the entire surface of the planet and have no equal on Earth (Carr 2006).

In conclusion, today Mars is extremely cold and dry by Earth standards. However, it is probable that the planet has not always been characterized by this frigid and hyperarid climate, but that in the past (around 4 billion years ago – Craddock and Howard 2002; Ramirez and Craddock 2018), the atmospheric pressure and the surface temperature were sufficiently high to allow the presence of surficial liquid water in the form of rivers, lakes, and possibly also oceans.

It is evident that this possibility would have very important astrobiological implications, since the presence of liquid water on a planet is commonly considered an essential factor for the origin and evolution of life on that body (Davis and McKay 1996; Nelson 2015). Also for this reason the study of the Martian paleoclimate is one of the most intriguing and debated issue in planetary science.

Basic Methodology

Observational Evidence

What the geological evidence clearly indicates is the presence on the Martian surface of many structures strongly suggesting fluvio-lacustrine processes. These structures include: layered deposits, alluvial fans and deltas, degraded and/or partially filled craters, putative ancient shorelines, and valley networks (see Ramirez and Craddock 2018 and references therein). The

latter are dendritic structures (recently mapped by Alemanno et al. 2018) whose morphology in most cases recalls similar terrestrial structures produced by precipitation (rain and snow), which – we have to remember – are currently impossible on Mars.

Due to this and other characteristics, valley networks are commonly considered the best evidence supporting paleoclimatic conditions substantially different from the current ones (e.g., Craddock and Howard 2002; Ramirez and Craddock 2018). Indeed, although ad hoc hypotheses have been suggested in the past to justify an origin of these structures in climatic conditions similar to the current ones (i.e., Gaidos and Marion, 2003), the hypothesis of a primitive atmosphere thick enough to allow, by means of a strong greenhouse effect, surface temperatures much higher than the current ones, seems to be able to provide a simple and unitary explanation of the origin not only of the valley networks but also of the aforementioned fluvio-lacustrine features associated with them.

The spectroscopic detection of clay deposits in many sites, where aqueous sedimentation very probably occurred, also strongly supports the notion of persistent water on ancient Mars (Bishop 2018; Ramirez and Craddock 2018), even if, according to Viennet et al. (2020), clay minerals are not always produced by aqueous alteration of preexisting silicates by surface water.

On the contrary, extensive carbonate deposits are lacking on the Martian surface (Christensen et al. 2001; Carr 2006) and this has often been cited by some authors (i.e., Christensen et al. 2001) as an evidence against a relatively warm and wet early Martian climate, since in principle, carbonates are expected to be very abundant on the surface of a planet with a CO₂-rich thick atmosphere (Carr 2006). However, more recent observations (Michalski and Niles 2010; Wray et al. 2016) have shown the widespread presence of carbonate-bearing rocks exposed from the subsurface by impact craters and troughs. According to Michalski and Niles (2010), these buried layered carbonates might be only a small part of a much more extensive ancient carbonate sedimentary record that has been buried by lava and/or airfall dust covering processes.

Key Research Findings

Results of the Paleoclimatic Models

These indications coming from geological and spectroscopic observations, substantially in support of an ancient Martian climate much less cold and dry than the present one, must be compared with those provided by paleoclimatic models. But unfortunately such models fail to give a univocal description of the past conditions of the planet.

Generally the traditional models, which assume an atmospheric composition not very dissimilar from the current one, i.e., of CO₂ and H₂O (see Wordsworth et al. 2013 and references therein), are not able to obtain surface temperatures high enough to allow fluvio-lacustrine activity. Actually, the maximum surface temperature achieved by such models for a 2 bar CO₂-H₂O atmosphere, fully saturated with water vapor, is ~250 K (Wordsworth et al. 2013), which is insufficient to support warm, wet conditions.

The only way to explain the geological/spectroscopic observations within such traditional models is to hypothesize that Mars was always cold and dry, but punctuated by short bursts of wetness, triggered by volcanism and/or meteorite impacts. In particular, according to Wordsworth et al. (2013), these two mechanisms would have caused episodic melting of glaciers located in the planet's highlands, causing the formation of the valley networks (this is the so-called “icy highlands scenario”). However, as suggested by Ramirez and Craddock (2018), these episodic warming mechanisms do not seem capable of producing the durations of warming and amounts of water necessary for the formation of the valleys and for the degradation of the ancient craters. In addition, according to the same authors, the icy highlands scenario is difficult to reconcile with a lack of evidence for widespread glaciations on the planet.

It is important to note that other “non-traditional” models have also been proposed which, under appropriate atmospheric conditions (pressure and composition) and/or surface conditions (albedo, thermal inertia), obtain global average temperatures close to zero centigrade (Mishna et al. 2013; Urata and Toon 2013; Godin et al. 2020; Kamada et al. 2020; Kite et al. 2021).

Among these models of particular interest is that of Kamada et al. (2020) which is based on an original idea of Ramirez et al. (2014) according to which the presence in the Martian atmosphere of traces of molecular hydrogen (H₂) would be able to produce an increase of the greenhouse effect due to CO₂ alone. This is because a hydrogen molecule (which is not a greenhouse gas), colliding with a carbon dioxide molecule, increases the absorption capacity in the infrared of the latter (measured by the so-called collision induced absorption cross section or CIA cross section), producing an additional heating of the atmosphere compared to the case of CO₂ alone.

The 3D model of Kamada et al. (2020) hypothesizes a planetary surface, with an ocean in the northern lowlands and some lakes in the southern highlands, below a CO₂-H₂O atmosphere with a certain additional percentage of H₂ of volcanic origin. In this partially saturated atmosphere, the water cycle is treated self-consistently by modeling the formation of H₂O clouds and their dissipation mainly due to precipitation. With this model, the Japanese team finds, for a 1.5 bar CO₂-H₂O atmosphere with 3% of H₂, an average annual temperature $T = 282$ K, while for the same atmospheric pressure and a percentage of 6% of H₂, they obtain $T = 294$ K.

To obtain these results, Kamada et al. (2020) use CIA cross sections for CO₂-H₂, theoretically derived by Wordsworth et al. (2017), which overestimate the absorption of radiation by CO₂ molecules compared to the experimental cross sections subsequently obtained by Godin et al. (2020). Consequently, the surface temperature for an atmosphere of 1.5 bar and 5% H₂ is approximately 12 K higher than that evaluated with the new CIA cross sections (Godin et al. 2020). By applying this correction to the above results, more accurate temperatures of 270 K and 282 K can be obtained in the case of a percentage respectively equal to 3% and 6% of H₂ in an atmosphere of 1.5 bar. These temperatures are easily able to support hydrological activity.

It should be noted that the values of atmospheric pressure and the percentage of H₂ that lead to this outcome appear to be consistent with the models of geological and physicochemical evolution of the

planet, in the light of what was discussed by Godin et al. (2020), about the atmospheric pressure, and by Deng et al. (2020), regarding the percentage of H_2 degassed by volcanic activity.

In conclusion, the results of this model and of all the nontraditional ones reported above suggest that around 4 billion years ago Mars was characterized by very different climatic conditions from the current ones. Compared to terrestrial standards they were, however, quite cold and also very dry, as suggested by various studies indicating an arid or semiarid Martian paleoclimate (e.g., Fukushi et al. 2019; Kamada et al. 2020). In other words, according to these scenarios, the past climatic conditions of Mars must have been similar (in terms of average temperature and precipitation) to those of the cold steppes of the Earth.

The duration of this period of mild climate experienced by Mars can be roughly estimated using as a reference the period of formation of the Martian valley networks, calculated as the difference between the age of last river activity of the oldest valley and that of the youngest valley listed by Fasset and Head (2008). The result is a mild period of 240 or 360 million years, according to the Neukum or Hartmann chronology, respectively. Obviously this is a conservative estimate, due to the relatively small number of valleys analyzed by Fasset and Head (2008). For comparison, the formation time of a single valley is of the order of tens of millions of years (Orofino et al. 2018).

This comparison suggests that the valleys were not all active at the same time. That is, in addition to the normal intermittence observed also on Earth in the individual valleys, on Mars the fluvial activity has affected the planet with a leopard spot distribution characterized by active areas that migrated on the surface as a result of roaming zones of precipitation (Hoke and Hynek 2009). It is also probable that some river systems experienced several successive episodes of water flow, interspersed with long periods of inactivity, as suggested, for example, by Jaumann et al. (2005) for an unnamed valley in the Lybia Montes region.

In any case, at some point, the declining volcanic activity was no longer able to compensate for the massive atmospheric losses measured by

the MAVEN mission (Jakosky et al. 2017). These losses, mainly due to the atmospheric sputtering by the solar wind, were caused by the disappearance of the magnetic field produced by the turning off of the planetary dynamo (Mangold et al. 2012). Therefore the planet has undergone a process of progressive cooling and drying up.

According to Rapin et al. (2021), the transition to the current frigid and hyperarid climate was not monotonic but instead it was characterized, at least locally (in the Gale crater), by a series of alternating wet and dry periods. Eventually, about 3 billion years ago, the planet stabilized in today's climatic conditions.

Future Directions

Future researches aimed to improve our knowledge on this subject should proceed in two directions: observation and modeling.

From the observational point of view, massive exposed carbonate deposits, which still escape detection, should be searched for.

On the other hand, the paleoclimate models should be improved carefully tuning the microphysics of the H_2O clouds, which are only approximately modeled. Furthermore low surface albedos, different from the present ones usually adopted in the models, should be also used to take into account the likely presence in the past of large sand-free areas composed of dark unweathered basalt (Mischna et al., 2013).

Finally, the presence of airborne dust should be included in some models, even if it is by no means certain that the dust, so important in the current paleoclimate, may have played an important role also in the ancient past of Mars.

Synonyms

[Ancient lakes](#)

Definition

A paleolake is a liquid water lake that existed in the past but no longer exists today. The existence of lakes in a previous geologic time period is known from the geologic features and geochemical signatures that are associated with the formation and maintenance of lakes. At sites of paleolakes, these features and signatures can be seen today long after the liquid water has disappeared from the surface. On Mars, there are many locations on the surface where evidence of past liquid water lakes is preserved. These locations are considered sites of Mars paleolakes. The Mars paleolakes date back to the early history of Mars, approximately 3–4 billion years ago.

History

There are numerous examples of geologic features on Mars that were created by the flow of liquid water across the surface. These geologic features include large outflow channels, small valley networks, deltas, inverted channels, conglomerates, and loose rounded gravel. These surface features seen today represent the work of liquid water flowing at different times in Mars past.

It is the small valley networks that supplied the liquid water to most of the Mars paleolakes. The direct source of the liquid water that flowed in these valleys is an area of active research. Two types of water sources are most frequently cited. These potential sources are precipitation (i.e., rain or snow) and groundwater discharge. Regardless of the source, any liquid water flowing on the

surface would have ponded, at least temporarily, in local areas of low elevation and thereby would have formed lakes.

The local topographic low points on Mars where liquid water collected and created lakes are most often ancient impact crater basins. Two of these impact craters are sites of detailed study by rover spacecraft: Gale Crater and Jezero Crater. Other paleolakes sites are not impact crater basins, but broad depressions in regions between impact craters. Most Mars paleolake sites are found at low latitudes between 30°N and 30°S, but some paleolake sites are seen at southern latitudes as high as 63°S (Goudge et al. 2012). In all cases the paleolake sites are in the oldest terrain on Mars (the ancient southern highlands). Because of the age of the Mars paleolakes and the likelihood of subsequent geologic activity, the paleolake sites in many cases may have been resurfaced since the site was a lake. The visible surface of the paleolake sites today may therefore not necessarily be the actual bed, or bottom surface, of the paleolake as it would have appeared right before the lake water was lost.

Even with the potential for resurfacing, Mars paleolakes and the geologic structures and materials they left behind are important sources of information for understanding the hydrologic and climatic history of Mars. Liquid water is generally not stable under the present environmental conditions at the surface of Mars. The small valley networks and other remnant fluvial features on the surface are therefore commonly taken as indications that the Mars paleoclimate was different from the climate of Mars today. The potential link between Mars paleoclimate and the small valley networks is intertwined with understanding the source of the water that flowed in the channels within the small valleys. Mars paleoclimate is an area of active research.

Depending on the climate of early Mars and the latitude of a given paleolake, the lake may have been an open water lake that was fully liquid, or it may have been an ice-covered lake in which liquid water existed under an ice cover that was a few meters thick (Kling et al. 2020). In either case, the paleolakes were sites where liquid water existed on the surface of Mars early in the history of the planet. The paleolake sites are therefore important

sites for astrobiological research, not just because of the singular importance of liquid water to life, but also because lake sediments not destroyed by resurfacing processes may preserve biological markers that can be used to test whether or not life ever developed on Mars.

[MMX](#)

Definition

Mars Moon Exploration (MMX) is a planned Mission from the Japanese Exploration Agency (→ JAXA) to study, using a pseudo orbit the moons of → Mars, → Phobos and → Deimos. The mission aims at sampling the soil of Phobos and brings back these samples on Earth for future analysis. At launch the spacecraft will comprise three different modules (Kuramoto et al. 2022): the propulsion module, the exploration module, and the return module to bring the samples to Earth. For a launch in 2024, the spacecraft will stay in the Martian system for about 3 years performing close observations of Deimos and Phobos, delivering a rover on the surface of Phobos and sampling material and → regolith from that moon. Samples are supposed to arrive on Earth about 2029.

History

MMX is based on the heritage gained with the missions → Hayabusa 1 and 2. Hayabusa 1 launched in 2003, explored the asteroid → Itokawa from 2005 up to 2007 and bring sample to Earth in 2010. Hayabusa 2 was directed to the asteroid → Ryugu. Launched in 2014 it studied the asteroid from 2018 to 2019, delivering samples on Earth in December 2020. The MMX program is the continuation of the exploration, by Japanese probes, of small bodies of the solar system.

Overview

The overall objective of the mission is to understand the origin of the Martian moons (to summarize: asteroid capture or giant impact) and to explain the evolution of the habitable planets of the solar system. Phobos is presently the main target of the mission. JAXA issued a

wide list of science objectives: (i) constrain Phobos origin using in situ observations and returned sample analysis, (ii) constrain Deimos origin by remote sensing close up observations, (iii) from the samples to extract data about the transport of material between the space bodies, (iv) understand the formation process of Mars and the evolution of the Martian system including an in depth study of the impact history, (v) determine the possible presence of water in the regolith of the moons.

To achieve this large set of objectives, the science payload comprises seven instruments.

The Light Detection And Ranging altimeter LIDAR is working with a laser (1064 nm) measuring height between 100 m and 100 km. At 100 km the vertical resolution is 22 m and the swath is of 50 m. It will measure the surface morphology enlightening the geological history of the moons.

The TElescopic Nadir imager for GeOmOrphology (TENGOO) and the **Optical Radiometer composed of CHromatic Imagers** (OROCHI) are two instruments working together.

TENGOO is a telescopic camera based on a Cassegrain telescope, working in a portion of the visible wavelengths with a spatial resolution set at about 40 m at an altitude of 20 km. The high-resolution images will be used to select and to document the sampling site and detect freshly exposed surfaces (if any).

OROCHI is a wide angle multi-band imager to acquire spectral images from the Martian moon surfaces with a resolution varying with the altitude and set at 20 m for an altitude of 20 km, 10 cm for an area of $100 \times 100 \text{ m}^2$ around landing sites of the rover, 1 mm for an area of $1 \times 1 \text{ m}^2$ around sampling sites. The instrument is based on seven independent imagers equipped each with a filter (respective wavelengths: 390, 480, 550, 650, 700, 800, 950 nm) and a panchromatic camera (400–900 nm) to be used during the sampling phase. It includes also a light-emitting diode to perform measurement even in the shadow of the spacecraft during the sampling phases.

Both instruments will be dedicated to the identification of the mineral components of the

surfaces as well as the observation of water and dust circulation in the Martian climate system.

The MMX Infrared Spectrometer (MIRS) is provided by the French Space Agency ($\rightarrow$ CNES) and build by a consortium led by the “Laboratoire d’Etude Spatiale et d’Instrumentation en Astrophysique” (France) (Barucci et al. 2020), the spectrograph is working in the range of 0.9–3.6 μm (with a 10 μm spectral sampling). The spatial resolution will be better than 20 m at an altitude of 20 km.

The Mass Spectrum Analyzer (MSA) is an ion mass spectrometer to measure the ionic environment of Mars and its moons. It detects ion in the range 1–100 amu with a resolution ($M/\Delta M$) better than 100.

The Mars moons Exploration with GAMMA rays and NEutrons (MEGANE) instrument, developed in collaboration with NASA, analyzes gamma-rays in the range of 0.4–8 MeV, thermal (0.01–0.5 eV), epithermal (0.5–0.5 MeV) and fast (0.5–7 MeV) neutrons. These observations will detect the major elements of the surface and the content of the shallow regolith in hydrogen atoms.

The Circum Martian Dust Monitor (CMDM) is a dust counter which will measure the dust grains over 10–20 μm in size. The detection is performed through a set of four piezoelectric sensors on a layer of the Multi-Layer Insulator made of polyimide. The shock wave analysis will characterize the impacting grain (Kobayashi et al. 2019).

The MMX Rover, jointly provided by the German space agency ($\rightarrow$ DLR) and the French space agency (CNES) (Michel et al. 2022), is an autonomous four wheel vehicle of about 25 kg on Earth (Sedlmayr et al. 2020). This solar powered rover is equipped with a laser Raman spectrometer, a thermal radiometer, two navigation cameras to provide stereo images and two so call “wheel cameras.” It will be dropped from the mothership and will land passively.

The ultimate goal of MMX is to retrieve around 25 g of regolith from Phobos and bring them to Earth. To achieve this objective JAXA will use two sampling approach: a coring system (C-sampler) developed in house by JAXA and a pneumatic sampler (P-sampler) provided under

the auspices of → NASA. The C-sampler is mounted on the robotic arm and can sample up to 10 cm beneath the surface, the retrieved material is then translated at the appropriate container. The P-sampler, derived from the system used with → OSIRIS-Rex (Zacny et al. 2020), is based on a pneumatic circuit collecting the regolith. The C samples will give insight up to a certain depth of the moon composition as the P samples will give an insight on the surface material and its evolution.

The return will use a system similar to Hayabusa probes. The mission is categorized by → COSPAR as an Unrestricted Earth Return (Coustenis et al. 2021).

Maser

Elizabeth Humphreys

ESO European Southern Observatory, Garching, Germany

Keywords

Active galactic nuclei · Comets · Evolved stars

Definition

An astrophysical maser (microwave amplification by stimulated emission of radiation) is a source of stimulated spectral ► [line emission](#). Maser emission is observed from circumstellar envelopes of evolved stars, ► [molecular clouds](#)/star-forming regions, active galactic nuclei, ► [supernova remnants](#), and comets and has been suggested for the Saturnian moons. It arises from molecules such as water (H₂O), hydroxyl radicals (OH), methanol (CH₃OH), formaldehyde (CH₂O), silicon monoxide (SiO), ammonia (NH₃), silicon sulfide (SiS), hydrogen cyanide (HCN), and atomic hydrogen recombination lines. Masers are compact, of high brightness temperature (see definition below), and often display narrow spectral line widths, polarized emission, and variability.

History

Astrophysical maser, or microwave laser, emission was first observed in the 1960s (Weaver et al. 1965). Initially, the nature of the emission

mechanism was not understood, and it was hypothesized that a new element, labeled “mysterium,” could be responsible. However, the spectral line was rapidly identified as a transition of the OH (hydroxyl) radical (Weinreb et al. 1965), and it was soon realized that the signal characteristics could be explained in terms of amplification by stimulated emission of radiation (e.g., Davies et al. 1967; Moran et al. 1968).

Overview

Astrophysical masers are regions of gas in which the amplification of radio or microwave radiation takes place. Maser amplification occurs at a wavelength corresponding to the energy difference between two energy states of a molecular/atomic species in the gas. In order for net stimulated emission to occur, a higher number of molecules must exist in the upper energy state than in the lower state. The populations of the levels are said to be *inverted*, and this is a prerequisite for maser action. The energy source that maintains the population inversion is known as the maser pump and can be radiative, collisional, or chemical in nature (or a combination of these processes). The radiation that stimulates maser action is amplified exponentially as a function of distance through the gas as long as the pump rate exceeds that of the maser stimulated emission rate. This is the *unsaturated* regime. As amplification continues, maser radiation may become sufficiently strong for the maser stimulated emission rate to rival that of the pump. The maser is then said to start to *saturate*, and amplification is linear as a function of distance through the source region. Maser radiation is partially coherent, highly beamed, and can display high degrees of polarization (Elitzur 1992; Gray 2011; Watson 2009; Dinh-v-Trung 2009).

Basic Methodology

Observationally, how is it possible to determine whether maser emission is being observed? One way is to measure the *brightness temperature* (the temperature of a black body in thermal

equilibrium which would produce the same intensity as that observed at the frequency of observation) of the emission. If the brightness temperature exceeds the temperature at which molecules can exist, a few thousand Kelvin, then the emission cannot derive from a thermally excited source. Masers often have brightness temperatures of $>10^9$ K and are compact compared with the scales of the astrophysical objects with which they are associated (e.g., stars, galactic nuclei). For example, masers have sizes of order 10^7 m in comets, and masers in galactic cores can have scale sizes up to 10^{19} m (Gray 2011). Other observational features that indicate maser emission are narrow, subthermal spectral line widths and time variability. Lines from different transitions of the same molecular species may also display ratios inconsistent with thermal emission. Maser polarization is typically interpreted as due to the Zeeman effect in the presence of magnetic fields.

Maser emission often involves molecular rotational transitions, with the masers typically pumped in warm, dense gas. For example, the best-studied SiO masers are those at 43 and 86 GHz ($\lambda = 7$ and 3 mm, respectively) originating from the two lowest-energy rotational transitions in each of the first and second vibrational levels. They are pumped at gas densities of $n(\text{H}_2) = 10^{10 \pm 1} \text{ cm}^{-3}$ and kinetic temperatures of $T_k \geq 1,500$ K (e.g., Elitzur 1992). The best-studied water masers are those at 22 GHz ($\lambda = 1.3$ cm) originating from the $6_{16}-5_{23}$ rotational transition. They are pumped in gas of $n(\text{H}_2) = 10^8-10^{10} \text{ cm}^{-3}$ and $T_k = 400-1,000$ K (e.g., Elitzur 1992).

When astrophysical objects associated with masers are imaged at high angular resolution, such as at submilliarcsecond resolution using very-long-baseline interferometry (VLBI), multiple maser features are often observed toward the same object. In addition, masers from multiple transitions of the same molecular species can amplify along the same regions of gas, and masers at different frequencies are often detected toward the same source. Finally, at least in the case of evolved stars and star-forming regions, masers from different molecular species are also often found toward the same object.

Key Research Findings

The circumstellar envelopes of oxygen-rich evolved low-mass and supergiant stars commonly harbor SiO, H₂O, and OH masers. Radio VLBI observations indicate that SiO masers occur close to the star, typically within about four stellar radii (Diamond et al. 1994). SiO maser emission has been detected from vibrational energy levels $v = 0-4$, up to at least the rotational transition $J = 8-7$ ($v = 344$ GHz; $\lambda \approx 1$ mm) in evolved stars, and SiO isotopologue masers are also observed (Soria-Ruiz et al. 2005). H₂O masers at 22 GHz form further from the star at a radial distance of, say, about ten stellar radii (e.g., Richards et al. 2012), with several other H₂O maser transitions also detected at frequencies up to 658 GHz. Main line (1,665 and 1,667 MHz) OH masers occur at similar radii to the 22 GHz H₂O masers but are believed to probe significantly less dense gas (Gray 2011). At much larger radii, typically 100 stellar radii, 1,612 MHz OH masers are observed. Polarized emission of the three molecular maser species has been interpreted to estimate circumstellar magnetic fields (Vlemmings 2007). ► **Proper motion** studies of the masers have been used to trace gas dynamics in the circumstellar envelope, with both outflow and infall detected in the SiO maser zone due to stellar pulsation. Toward the less common carbon-rich stars, HCN and SiS masers have been observed.

Star-forming regions in molecular clouds support a variety of maser species, with methanol, water, and OH masers the most frequently detected. Maser emission is observed from both low- and high-mass forming stars; however, stellar masses significantly $>1 M_{\text{sun}}$ are favored (Gray 2011). Water masers at 22 GHz are often seen in protostellar outflows associated with shocked gas and are more rarely thought to be associated with accretion disks. Other water masers, including those at frequencies of 183, 321, and 325 GHz, have also been detected. Methanol masers in star-forming regions are divided into two types, Class I and Class II, depending on the transitions present. Class I methanol masers are primarily collisionally pumped and may trace outflow interactions with

dense molecular gas. Class II methanol masers tend to be associated with HII regions, with the best-studied transitions occurring at frequencies of 6.7, and 12.2. GHz. Methanol, OH (mainly 1,665 and 1,667 MHz lines), and H₂O masers are often present in the same source, although water and methanol masers usually appear in different regions from each other. Again, maser polarization is used to determine magnetic field characteristics, with fields as high as 40 mG seen in OH masers (Fish 2007). Rarer masers in star-forming regions include ammonia, formaldehyde, and SiO (currently detected in three high-mass star-forming regions only).

► **Supernova remnant** (SNR)/molecular cloud interactions also give rise to maser emission. OH 1,720 MHz masers have been detected from ~ 20 galactic SNRs, that is, 10% of the galactic sources (Brogan 2007). Methanol maser emission at 95 GHz has also been detected toward one SNR. Hot stars MWC 349A and Eta Carina harbor H-atom recombination masers over a range of frequencies (see, e.g., Gray 2011).

Extragalactic maser emission, in some cases referred to as *megamaser* emission, is most commonly detected from 22 GHz H₂O and OH 1,665 and 1,667 MHz lines, although formaldehyde maser emission at 6 cm is also known. OH megamaser emission occurs from nuclear starburst activity, on scales of about 100 pc, whereas 22 GHz water maser emission is observed on (sub)parsec scales and traces the central engines of active galactic nuclei (AGN) (Pihlström 2006). Over a hundred extragalactic water maser sources are now known, including a ► **redshift** $z = 2.64$ detection magnified by gravitational lensing (Impellizzeri et al. 2008). Detections of extragalactic methanol masers are limited to the Large Magellanic Cloud and appear to be similar to Galactic methanol masers.

In the Solar System, masers have been detected from cometary comas. Cometary OH masers have a UV pumping mechanism and have been observed from at least 16 comets, including ► **Comet** Hale-Bopp. Water masers at 22 GHz have also possibly been detected. Water maser emission was detected after the impact of Comet Shoemaker-Levy 9 with Jupiter and has also been

reported from the Saturnian moons Hyperion, Titan, Enceladus, and Atlas (Pogrebenko et al. 2009). Molecular laser features from CO₂ at 10.33 μm were detected in the atmospheres of Venus and Mars. Searches have also been performed for molecular maser emission associated with exoplanets, but to date no emission sources have been reported.

Applications

Masers are used as tools to probe the physical conditions, kinematics, and magnetic fields of astrophysical sources at high angular resolution. Maser line ratios constrain radiative transfer models to determine gas temperatures and densities. ► [Proper motion](#) measurements enable tracing of gas kinematics. Maser polarization, when attributed to the Zeeman effect, can be used to determine magnetic field strength and morphology characteristics. Masers can be used to measure dynamic masses and to provide distance estimates. In the case of water masers in active galactic nuclei, this has led to their use for planned high-accuracy estimation of the Hubble constant, which may lead to constraint on the nature of dark energy (Braatz et al. 2009; Greenhill et al. 2009). OH masers are used to search for variations in the fundamental “constants” over cosmological time (Darling 2003). Galactic trigonometric parallax measurements trace the number and location of the spiral arms in the Milky Way and the distance of the Sun from the Galactic Center (Reid et al. 2009).

Future Directions

New instruments will revolutionize the use of masers as diagnostic probes. The Atacama Large Millimeter/Submillimeter Array (ALMA) will perform imaging up to about 950 GHz, enabling observation of high-frequency maser lines at angular resolutions of better than 10 mas. At low frequencies (foreseen 0.1–25 GHz), the Square Kilometre Array (SKA) will provide very high sensitivity, allowing for searches for distant masers in the early universe.

While extinctions are quite common in nature, mass extinctions are relatively rare events. Five mass extinctions have been recorded in the last 500 Ma (Phanerozoic). It is now suggested that a sixth one, caused by increased anthropogenic pressure on the environment, is ongoing. Catastrophic agents, such as meteorite impacts, and environmental agents, volcanic eruptions, ► [glaciations](#) and global climatic changes, and variations of oxygen concentration in seawater, could explain mass extinctions, though the exact mechanisms remain relatively unknown. These biotic crises must be viewed as important steps in the evolution of life. During the post-event recovery, the vacant ecological niches are filled by new species, like the mammals that became dominant after the dinosaur extinction at the well-known ► [KT boundary](#).

Mass Extinctions

[Biotic crisis](#); [Extinction event](#); [Extinction-level event](#)

Definition

A mass extinction or extinction event refers to an abrupt decrease in the number of species in a short span of geological time. The term is different from simple *extinction* that denotes in ecology the disappearance of an organism or group of *taxa*.

Overview

Several major biotic crises or mass extinctions mark the evolution of life during the Phanerozoic (Fig. 1). During these events and over a rather short time frame, a large proportion of the existing species on land and in the oceans suddenly become extinct. A major and brutal decrease in the diversity and abundance of life characterizes these extinction levels. The development of new species follows.

In the last 500 Ma, there have been five large mass extinctions that eliminated more than half of the species inhabiting the Earth. The five recorded mass extinction events occur at the end of the Ordovician (~444 Ma; Hirnantian stage), in the Late Devonian (~370 Ma), at the Permian-Triassic boundary (~251 Ma), at the Triassic-Jurassic boundary (~200 Ma), and at the most studied Cretaceous-Tertiary boundary (often labeled as the ► [KT boundary](#) ~65 Ma) (Raup and Sepkoski 1982; Hallam and Wignall 1997).

Late Ordovician Extinction

A major global cooling of the Earth's climate followed by rapid ► [glaciations](#) could have triggered the Late Ordovician extinction. Extinction has been linked with environmental changes

Mass Extinctions,

Fig. 1 Genus diversity in the Phanerozoic time (542–0 Ma). The *light gray* plot shows the number of known marine animal genera versus time from Sepkoski (2002), converted to the 2004 Geologic Time Scale. The *dark gray* plot shows the same data, with single occurrence and poorly dated genera removed. The trend line is a third-order polynomial fitted to the data. (After Raup and Sepkoski (1982), redrawn by M. Laithier, UQAM)

accompanying the glaciation of the supercontinent ► [Gondwana](#) that comprised most of the landmasses at that time. Sixty percent of genera disappeared from the geological record, and it is estimated that 85% of genera inhabiting the Earth became extinct. This is the second largest mass extinction after that of end-Permian. The extinction occurred as two 2 Ma-long phases, one at the beginning and the other toward the end of the Hirnantian stage. The first is associated with sea-level regression and climate deterioration at the onset of the glaciation of Gondwana, the second with sea-level transgression caused by continental flooding and accompanied by anoxia as the ice caps melted.

Late Devonian and the Permian-Triassic Extinction

The processes leading to the Late Devonian and Triassic-Jurassic biotic crises are still poorly documented. The Devonian extinction took place in the Frasnian-Famennian boundary, about 364 Ma ago and lasted 2–3 Ma. Glacial deposits in Brazil and in the Peru-Bolivia Altiplano of Devonian age suggested that another glaciation on

the Gondwana supercontinent could have triggered an episode of global cooling. This is also supported by the fact that warm water marine species were the most severely affected by this glaciation.

The greatest mass extinction at the Permian-Triassic boundary is often called the “Great Dying” because ~70% of land and more than 90% of marine species disappeared. This period is characterized by some of the best evidence recorded in the European geological record of extensive sea-level fall quickly followed by rise, and these global changes no doubt contributed to the extinction. There is no evidence of a meteorite impact, but the event was synchronous with Siberian flood volcanism, the largest-known continental volcanic province. The magmas of this province intruded carbonates and sulfate-rich sedimentary rocks, which released large amounts of CO₂ and SO₂ when heated, and the toxic cocktail of sediment- and magma-derived gases probably contributed to the extinction.

KT Boundary

The most famous ► [KT boundary](#) saw the demise of the dinosaurs on land and of the ammonites and

the marine reptiles in the oceans. Across this interval, ~60% of the fauna and flora on Earth went extinct, and in particular, the marine calcareous microplankton was drastically affected. The impact of a ~10–12 km asteroid on the Yucatan peninsula is widely accepted as one of the major causes of this mass extinction. This impact formed the ~200 km [Chicxulub crater](#) and spread ejecta material all around the globe. Worldwide, the KT boundary layer is marked by the characteristic positive iridium anomaly, generated by the presence of meteoritic material. The largest phase of Deccan flood volcanism in India erupted 67 Ma ago, synchronously with the KT event. Single lava flows extended for more than 1000 km and covered most of India of continental flood basalts, and huge emissions of greenhouse and toxic gases were associated with the eruptions. Possibly, both impact and volcanism contributed to this mass extinction (Courtillot 1999).

Precambrian Mass Extinctions

Precambrian mass extinctions have been proposed such as during the Vendian period (605–543 Ma). This extinction largely affected stromatolites and acritarchs, and it has been correlated with a large glaciation event that occurred about 600 Ma ago. This event was of such severity that almost all microorganisms were completely wiped out. Whether the Vendian event was a major extinction is currently under debate. Older extinctions are impossible to evaluate because the fossil record is less well preserved and abundant. It is likely that mass extinctions occurred during global climate events such as Snowball Earths and in earlier times during the Archean and [Hadean](#) eons, if life already inhabited the Earth. Indeed, if microorganisms were already present during the Hadean, intense meteoritic bombardment, the catastrophic volcanism, and rapid changes in the physicochemical conditions of oceans (acidity, temperature, and salinity) could have driven repeated mass extinctions.

Basic Methodology

Apparent extinction intensity, i.e., the fraction of genera going extinct at any given time, has been

reconstructed from the fossil record. Abundance and biodiversity estimates are directly related to the quantity of rock available for sampling from different time periods, and thus, this methodological approach can create artifacts. The development of the “chemostratigraphy,” i.e., the study of the variation of chemistry within sedimentary sequences, particularly the variations in the stable isotopes of C, S, and N contained in kerogens or [radiogenic isotopes](#) (Sr, Os), gives a valuable support for determining mass extinction horizons (Marshall 1992; Brenchley et al. 1994). Carbon isotope values ($\delta^{13}\text{C}$) from rocks, fossils, and biomarkers record global changes in the carbon cycle. This implies changes in carbon inputs (e.g., riverine vs. marine), outputs (e.g., methane hydrate emissions), organic productivity, and carbon burial. All five of the major Phanerozoic mass extinction events are matched by significant carbon isotopic excursions. The $\delta^{13}\text{C}$ data of both carbonate and organic carbon from numerous sections worldwide reveal a positive $\delta^{13}\text{C}$ excursion shortly after the first pulse of extinction at the end of the Ordovician. This positive $\delta^{13}\text{C}$ excursion is interpreted to have resulted from high primary productivity or from the [weathering](#) of carbonate platforms that were exposed when sea level fell during the glaciation. Negative excursions found associated with the end-Permian are interpreted to record collapse in primary productivity, massive release of methane from hydrates, or release of gases from sedimentary rocks heated by basaltic magmas (Ganino and Arndt 2009).

Future Directions

Two main questions need to be addressed:

1. Can we identify mass extinctions in the earlier geological record of the Earth?
2. Are there common or multiple causes to mass extinctions?

The first question is difficult to answer because the answers must be sought from a period when the fossil record is almost totally absent or rare. Chemostratigraphy is difficult to apply because

the diagenetic effects on the isotopic signatures and because Precambrian biogeochemical cycles of C, N, S, and other elements were possibly different than in post-Cambrian times and thus the isotopic signature rather complicated to interpret.

Several authors try to answer the second question by identifying possible periodicity in the extinction events and relate them to common geological or environmental changes. This is an old approach used since Cuvier's theory of catastrophism and still largely debated (see Hallam and Wignall 1997). Recent robust statistical estimates suggest 62 ± 3 Ma cycles (Rohde and Muller 2005). This cycle could be related to the passage of the Solar System into molecular clouds increasing meteoritic or cosmic dust showers or to perturbations of the Oort cloud increasing the risk of cometary impact on the Earth. Other theories suggest a relation with the episodic rise of the global-scale mantle plumes that cause flood basaltic volcanism. These huge basaltic volcanic eruptions are synchronous with all known mass extinction levels (except for the end-Ordovician event), within the limit of error of modern dating techniques (Courtillot 1999).

Mass Loss Rate

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The mass loss rate quantifies the rate at which a star loses its matter as a result of various effects. It corresponds to an ejection of matter, usually called ► [stellar wind](#), which happens all along the star's life but especially in the final stage (post-AGB phase). Massive stars exhibit very large mass loss rates. The unit is kg s^{-1} or more usually $M_{\text{sol}} \text{ year}^{-1}$, where M_{sol} is the mass of the Sun.

Definition

Mass spectrometry is an analytical method used to identify and quantify chemical species based on their molecular mass. It is also widely used to determine the isotopic abundances (isotopic ratios) of various elements. The mass to charge ratio of ionized molecules is determined by their motion traveling through electromagnetic fields. Elemental composition and chemical structure of molecules are also estimated using the higher mass-resolving power of the system and interpretation of the mass spectrum of fragment ions. By choosing appropriate ionization methods, mass spectrometry provides information other than mass, such as the polarity of molecules. Imaging capability and chiral identification are promising features of mass spectrometry for astrobiology.

Overview

Mass spectrometry (MS) is capable of analyzing any substance, once sample molecules are ionized. By this generic feature, which is superior to other methods of chemical analysis, MS has

become a common instrument for astrobiology. Ordinary MS requires a volatilization process prior to analysis. However, many bio-associated molecules are hard to volatilize even at relatively high temperature. The strong intermolecular interaction of biomolecules, originating in their strong polarity, tends to produce charring, not volatilization, at high temperature. The innovation of soft ionization, appropriate for such substances in principle, leads MS to be a highly powerful tool for astrobiology with many new applications, both on the ground and in space.

The most common use of MS is to detect and characterize organic substances of astrobiology interest. It is essential for understanding prebiotic chemical evolution and ultimately for getting direct evidence of extraterrestrial life, if any. Analysis of the isotopic composition of substances is a unique capability of MS. The isotopic composition of bioelements in fossils can provide evidence of activities of extinct living organisms, based on the isotope effects on biochemical reaction rates. Spatially resolved MS techniques have been developed recently. This also opens new horizons for astrobiology.

Basic Methodology

Mass spectrometry consists of three steps, i.e., ionization, mass separation, and ion detection.

Electron impact (EI) is a common ionization method. Electrons, with energies at 50–100 eV, hit sample molecules to ionize them. Molecules should be volatilized before EI. Most biogenic molecules are hard to volatilize and require chemical modification to increase vapor pressure. Thermal ionization, inductively coupled plasmas (ICP), and sputtering sources are also widely used to determine isotopic abundances.

Another approach for biomolecules is soft ionization. Electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) are typical soft ionization methods. ESI ionizes molecules by spraying finely charged droplets in a strong electric field. Desorption electrospray (DESI), a derived method of soft ionization,

produces ions directly from a surface. MALDI ionizes biological substances through desorption of molecules after energy deposition by a laser to the matrix.

► **Photoionization** can provide highly selective ionization, useful in case the ionization potential of the target molecule is lower than the energy of the irradiating photon, while that of other molecules is higher than the photon energy. Because aromatic compounds have low ionization potentials, poly-aromatic hydrocarbons (PAHs) are selectively ionized by ultraviolet lasers in this way.

An imaging capability of MS has been developed for several ionization methods. Secondary ionization MS (SIMS) is based on excitation of sample molecules by the incidence of primary ion beams. Scanning of the primary beam on the substrate creates spatially resolved MS. Ionization methods employing lasers are capable of imaging. DESI can analyze the spatial distribution of substances at less resolving power.

In the second step of MS analysis, charged molecules can be separated by the electromagnetic force. In the early era of MS, deflection of traveling ions in a magnetic field has been the common principle of MS (magnetic sector MS). The trajectory of ions in a quadrupole electric field, either two dimensional (quadrupole MS) or three dimensional (ion trap and orbitrap), stays within a defined space, if the operational parameters of the quadrupole field are tuned to a specific m/z . Time-of-flight MS (TOF MS) generates a mass spectrum by measuring the traveling time of ions after pulsed acceleration. Ion cyclotron resonance (ICR) is based on the cyclotron motion of charged particles in magnetic fields and its dependence on m/z .

Tandem MS (MS/MS) is a popular configuration to obtain the spectrum of fragment ions. The fragmentation spectrum provides information about chemical structure, mostly the sequence of monomers.

Ion detection is the final stage of mass analysis. A resonance method such as ICR detects ions by their image current, which is induced by the motion of the ions. Another type of mass analyzer uses a secondary electron multiplying device to gain high sensitivity for the detection of ions.

Key Research Findings

Mass spectrometry in ground-based astrobiological studies:

The organic substances found in a Martian meteorite, ALH84001, marked the first direct evidence of organic molecules brought from an extraterrestrial planet. It was analyzed by a combination of infrared and ultraviolet lasers. Evaporation of the sample was made by infrared radiation, and successive shots of UV laser light produced photoionized PAHs. It has been proposed that the aliphatic side chains of the PAHs suggest a biological origin of these PAHs, although others have claimed these are in fact contaminants introduced from Antarctic ice.

An extraterrestrial amino acid, glycine, was found in the captured dust of a comet by gas chromatography/mass spectrometry (GC/MS). The Stardust sample was hydrolyzed and chemically derivatized in order to increase the vapor pressure for GC/MS analysis. The isotopic abundance of ^{13}C in the glycine supports its extraterrestrial origin. This result bears on the understanding of the chemical evolution in our solar system and the possible contribution of comets in supplying prebiotic organics to initiate life on Earth.

Mass spectrometry employed in space astrobiology missions is summarized below.

- **Mars:** The two ► **Viking** landers (1976) had MS to analyze the Martian atmosphere and its isotopic composition. Even though the composition of the atmosphere can be estimated remotely from Earth, on-site MS analysis is essential to provide isotopic information. The observed data was also used to determine the origin of some Martian meteorites, which contain trapped samples of the Martian atmosphere. The history of Mars' lost atmosphere can be elucidated from measured isotopic ratios. GC/MS also performed a biological experiment on Viking.
- **Phoenix** landed on a polar region of Mars in 2008. A Thermal and Evolved Gas Analyzer (TEGA) was included in the scientific payload of Phoenix. A surface sample was heated in its

oven up to 1000 °C, and volatiles from the sample were analyzed by a magnetic sector MS. The dynamic range of this system would have been able to detect organic molecules at 10 ppb level.

- Mars Science Laboratory (MSL) is exploring habitability of Mars since landing of the Curiosity rover in 2012. Quadrupole MS with GC is a part of the Sample Analysis at Mars (SAM) instrument. Analysis of gas released from heated rock samples suggests a chemical environment in the past related to potential habitability.
- ► [Titan](#): The Cassini-Huygens mission to Saturn included the Huygens probe that descended to Titan in 2005. The GC/MS on the Huygens probe analyzed the atmospheric composition of Titan, which is dominated by CH₄ and N₂. The isotopic ratios were analyzed for those atmospheric species.
- Comets: Giotto explored ► [Comet Halley](#) with MS in 1986. Chemical species, both neutral molecules and ions, were analyzed during its flyby. Comets are considered to be a source of prebiotic molecules. Other than the major components H₂O, CO, and CO₂, both H₂CO and HCN were found.

Applications

Mass spectrometry is a powerful tool to detect and characterize biogenic and prebiotic substances and thus to find signatures of life on extraterrestrial bodies and to elucidate their environmental factors. The generic features and high sensitivity of MS make it a common science payload of many space missions. Isotopic information available by MS is essential to differentiate biotic or abiotic origin and to understand a planetary environment and its history for astrobiology.

Future Directions

The following space missions with MS instrument are now ongoing or in preparation.

A part of the ► [ExoMars](#) mission will be launched in 2022. The Mars Organic Molecule

Analyzer (MOMA) is a scientific payload of this portion of ExoMars. It aims to detect organic substances in deep (2 m) drilled samples. Ion trap MS with a laser desorption ion source enables detection of biogenic or prebiotic organics without the heating and charring of samples experienced in former missions.

Mass spectrometry can be further adapted for astrobiology in several ways.

To gain higher sensitivity to detect biogenic and prebiotic substances is essential for astrobiology. Even if organics will not be found at all, the extended limit of detection will contribute to assessing working hypotheses for the origin of life. Choosing proper soft ionization processes for biogenic and prebiotic molecules will bring new findings through the high signal-to-noise ratio and increased sensitivity.

In addition to the choice of ionization, preprocessing of samples is an important step in astrobiology MS. One solution is direct ionization from a substrate surface. Another approach is preprocessing to convert complex sample substances to their constituent molecules. ExoMars implements a payload, Urey, to detect organics on the Martian surface. The sample will be exposed to subcritical (near the critical point) aqueous extraction. Organics are leached out from the solid sample, and macromolecules are hydrolyzed to constituent molecules. Digested smaller molecules, if similarly processed, keep information specific to the original biological system and can be mass analyzed by soft ionization. For astrobiology, a combination of liquid chromatography and MS (LC/MS) is by its nature a more suitable approach compared to GC/MS.

The imaging capability of MS enforces its strength by high sensitivity. Compared to the ordinary bulk analysis, spatial information from MS provides structural information on biological forms at scales from the microscopic cellular level to mesoscopic systems.

The homochirality of amino acids and sugars, if found on extraterrestrial bodies, is a factor that would distinguish biogenic origin from abiogenic substance. Even separation of optical isomers can be made by liquid chromatography/MS.

Mass spectrometry continues to be a powerful tool for astrobiology.

Mass-Luminosity Relation

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

The mass-luminosity relation for ▶ [stars](#) is an empirical correlation observed between the mass M and the luminosity L of stars on the ▶ [main sequence](#) of the ▶ [Hertzsprung-Russell](#) diagram. It has the form $L \propto M^K$, with $K \sim 3.5$ as an average value. The lowest mass stars ($0.1 M_{\odot}$) are about 2,000 times less luminous than the Sun, whereas the most massive ones ($100 M_{\odot}$) are 1,000,000 times more luminous. The relation is due to the fact that stars in hydrostatic equilibrium – supported against self-gravity by their internal pressure – are hotter when they are more massive; therefore, their material radiates more strongly than in the case of lower mass stars.

Master Equation Models

Eric Herbst

University of Virginia, Charlottesville, VA, USA

Definition

Master equation models can be employed for interstellar grain surface chemistry when there are few reactive species on individual grains. For example, if there are fewer than 2 hydrogen atoms on a grain, reactions to form molecular hydrogen are impossible yet are included in rate equation

treatments when not modified. Instead of normal rate equations, which include only one time derivative per species, master equation treatments include different equations for the time derivatives of the probabilities of specific numbers of species per grain. For example, consider a grain surface with initial probabilities $p(n_H)$ for n_H hydrogen atoms. The differential equations for the time derivatives of the $p(n_H)$ values equate the derivatives to the sum of positive (gain) and negative (loss) terms. Consider a specific number of hydrogen atoms n_H' . Positive terms enhance the probability $p(n_H')$ by adding H atoms to a grain with fewer atoms or by reducing the number of H atoms on a grain with initially more than n_H' atoms, while negative terms do the opposite. Summing over the solutions of the equations for each $p(n_H)$ and $p^2(n_H)$ as a function of time leads to an average value $\langle n(H) \rangle$ and its fluctuation, which can be compared with the concentration of the rate equation method (Biham et al. 2005).

With more than one species on a grain, however, the probabilities become joint probabilities which include numbers of each species, i.e., $p(n_H, n_O, n_{CO}, \dots)$. The large number of different probabilities leads to a large number of equations (strictly infinite) which requires approximations such as only using the master equation treatment on species of low abundance but important reactivity and/or setting an upper limit on n for either the total number of reactive species or for specific species (Stantcheva and Herbst 2004; Le Petit et al. 2009). Another approximation, known as the moment approach, in which the master equation is expanded in a series based on moments, has also been used. In general, the master equation technique for problems, in which small numbers of reactive adsorbates such as atomic hydrogen exist per grain, has been replaced by Monte Carlo techniques, in which similar results are obtained but by a very different technique. Here pseudo-random numbers from 0 to 1 are called to choose a process and its rate involving individual species, which occurs in a given time based on a distribution. (See entries for macroscopic Monte Carlo models and microscopic Monte Carlo models.) It should be noted that mixed gas-grain simulations can contain the master equation approach for the

granular chemistry and a deterministic rate equation approach for the gas-phase chemistry. If, on the other hand, a Monte Carlo approach is used for the granular chemistry, such an approach must also be used for the gas-phase chemistry.

Mated Bioburden

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

In ► [planetary protection](#), the term “mated ► [bioburden](#)” is used to indicate the viable

microorganisms that are carried on spacecraft surfaces that are in contact with each other (mated) and joined by fasteners (e.g., bolt, screw, rivet, clip, and clamp) rather than by adhesives (surfaces joined by adhesives would result in ► [Encapsulated bioburden](#)).

Location of a microorganism on a mated surface is thought to reduce the rate of water loss during heat sterilization processes (relative to surface bioburden) that is one of the causative factors for cell death during ► [DHMR](#). The lethality of DHMR processes on mated bioburden is taken as half the lethality for bioburden on exposed surfaces.

Materialism

Christophe Malaterre

XInstitut d'Histoire et Philosophie des Sciences et Techniques (IHPST), Université Paris 1-Panthéon Sorbonne, Paris, France

Keywords

Dialectical materialism · Ethical materialism · Historical materialism · Matter · Metaphysical materialism · Substance

Synonyms

[Physicalism](#)

Definition

In philosophy, materialism is most often taken as a metaphysical thesis according to which everything that exists is matter or results from matter (including life and consciousness); this thesis offers a monist ontology that typically contrasts with idealism, dualism, and ► [vitalism](#). Materialism also refers to an ethical doctrine according to which the material well-being (including wealth, health or pleasure) is to be sought after. In social sciences, historical materialism is the Marxian thesis that historical and social phenomena are determined by economic facts; it is a particular case of dialectical materialism that construes the universe as a whole within which objects cannot be understood in isolation of one another.

Overview

The nature of what exists is an old question that goes back to ancient Greek philosophers such as Thales or Lucretius. In the seventeenth century, Hobbes and Gassendi typically represented the materialist tradition, in clear opposition to Descartes' dualism. The word "materialism" is said to have appeared for the first time in writings of Boyle. The doctrine is further developed in the eighteenth century by several French enlightenment thinkers (e.g., Meslier, de la Mettrie, Baron d' Holbach, Diderot). Broadly, materialism holds that "everything is matter," and that, as a consequence, all phenomena, including life and consciousness, result from matter and material interactions. Materialism offers a monist ontology in which matter is the only substance, in contrast with idealism or spiritualism, and with pluralist ontologies such as dualism or vitalism.

The metaphysical thesis of materialism raises interpretation and truth questions: what does it mean to say that *everything* is matter? What is *matter*? Is materialism *true*? The nature and

definition of matter, in particular, have been much controversial. Traditionally referring to the type of tangible substance that we are broadly familiar with, the concept of matter has considerably evolved with the physical sciences, in particular relativity and quantum field theory, possibly including “dark matter” and “dark energy.” Some prefer now to use the term ► **“physicalism”** instead of “materialism,” as exemplified by much of the contemporary debate in analytic philosophy, also linked to questions of supervenience, emergence, and ► **reductionism**, especially in philosophy of mind and philosophy of biology.

In moral philosophy, materialism refers to a practical doctrine according to which material considerations are the most worthy in one’s life: material well-being, wealth, health, or pleasure. Such an ethical materialism is present in Baron d’Holbach’s *System of Nature* and Haeckel’s *Natürliche Schöpfungsgeschichte*, and can be traced back to Epicurus.

The concept of historical materialism, first articulated by Engels and Marx, refers to the thesis that change in human societies originates in the economic means of production of the necessities of life; social classes, political structures, and other noneconomic elements of a society are seen as an outgrowth of the economic activity. Historical materialism fits as a particular case of dialectical materialism, a doctrine that construes the universe as a whole, constituted by matter in movement and within which qualitative transitions result from quantitative changes and from interactions of objects with one another. Evolutionary biologists such as Gould and Lewontin have defended dialectical materialism as a heuristic methodology.

Mathilde

Stefano Mottola

German Aerospace Center (DLR), Institute of Planetary Research, Berlin, Germany

Definition

(253) Mathilde is a dark, primitive Main Belt asteroid classified as a C type. The body, which is approximately 50 km in size, was the third asteroid to be visited by spacecraft when the Discovery space probe NEAR Shoemaker flew by in 1997 on its route to NEA Eros. Pre-encounter ground-based observations performed during the 1995 apparition have allowed an unusually long rotation period in excess of 17 days to be determined. In addition, those observations have detected multiple periodicities in the body’s lightcurve, which have been interpreted as the signature of free precession. Although NEAR Shoemaker could only image one hemisphere of the body, due to its slow rotation and to the fast flyby geometry, the bulk density of the body could be estimated to 1.3 g/cm³. This value, which is lower than the density of analog carbonaceous chondritic meteorites, implies comparatively

high porosity. The visible surface of the body is characterized by several very large impact craters, two of which have diameters comparable to the object's radius. The very fact that the body escaped destruction as a consequence of such large impact events, in addition to its low bulk density, is interpreted as Mathilde having the structure of a rubble pile.

Mean Free Path

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The mean free path is the mean travel length of an elementary particle (photon, atom, molecule, ion) between two successive interactions with other particles of another or of the same type.
 ► [Scattering](#) of photons in a dusty medium and
 ► [diffusion](#) of molecules are examples of phenomena where the notion applies. Unit: m.

Mean Motion Resonance

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

In planetary dynamics, a mean motion resonance refers to a commensurability between orbital

frequencies. If the ratio of the orbital periods of two (or more) planets or satellites is close to the ratio of two small integers, mutual perturbations may cause the orbits to evolve in ways not expected from secular evolution. Mean motion resonances have the potential to be protective or destructive, depending on the relative orientation of the orbits. For example, Neptune and Pluto's orbital period ratio is close to $2/3$, and the orbits actually cross, but resonance forbids the two planets from ever meeting at this crossing. Note that mean motion resonances do not depend solely on the orbital period ratio of two objects but also on their orbital alignment and phase.

MEarth

Emeline Bolmont
Observatoire de Genève, Université de Genève,
Chemin Pegasi 51, 1290, Sauverny, Switzerland

Definition

The MEarth project (Nutzman and Charbonneau 2008) is an all-sky transit survey done using small 40 cm robotic telescopes, located in the northern hemisphere at the Fred Lawrence Whipple Observatory in Arizona (USA) and in the southern hemisphere at the Cerro Tololo Inter-American Observatory, just east of La Serena (Chile). MEarth was built to find planets in the habitable zone of very low-mass stars (M-stars, the "M" of MEarth). The first MEarth planet, GJ 1214b, was detected in 2009 (Charbonneau et al. 2009). To date, the most remarkable discovery of MEarth is one of a super-Earth planet of 1.7 Earth radius:

LHS-1140b (Dittmann et al. 2017). It sits comfortably in the habitable zone of its star.

Thanks to the groundbreaking MEarth project, other surveys targeting very low-mass stars have started. In particular, SPECULOOS, whose prototype TRAPPIST allowed the discovery of the TRAPPIST-1 system, which hosts three small planets in the habitable zone of a very low-mass star.

MEED

Gerda Horneck

DLR German Aerospace Center, Institute of Aerospace Medicine, Radiation Biology, Köln, Germany

Synonyms

[Microbial Ecology Evaluation Device](#)

Definition

The Microbial Ecology Evaluation Device (MEED) is a device to expose different biological systems to selected parameters of outer space (space vacuum, solar UV radiation, and/or cosmic radiation).

Overview

The Microbial Ecology Evaluation Device (MEED) is an exposure facility for a variety of ▶ [microorganisms](#) (Table 1) that were transported with the Apollo 16 spacecraft to the Moon and back to the Earth. It is, so far, the only device that has exposed microorganisms to the outer space conditions beyond the Earth's magnetic field. During the extravehicular activity phase of the transearth coast, that is, return trip to the Earth, MEED was deployed outside the Apollo 16 capsule on the distal end of a television boom, opened, and oriented perpendicular to the Sun's rays. After 10 min of Sun exposure, the MEED was closed again and returned back to the Command Module for return to Earth. MEED was also equipped with UV dosimeters, and passive nuclear track detectors, and thermoluminescent dosimeters for monitoring cosmic rays.

MEED, Table 1 Biological assay systems of MEED (Taylor 1975)

Biological system	Phenomenon studied	Assay system
<i>Bacillus subtilis</i> spores	Genome alteration	Spore production
<i>Bacillus subtilis</i> spores	UV- and vacuum-sensitivity	Colony formation
<i>Bacillus thuringiensis</i>	α , β , and δ toxin production	<i>Sarcina flava</i> , house fly, silk worm, and crystal assay
<i>Aeromonas proteolytica</i>	Hemorrhagic factor production	Guinea pig and hemoglobin

Melanins

Marco d’Ischia and Paola Manini
Department of Chemical Sciences, University of Napoli Federico II, Naples, Italy

Keywords

Eumelanins · Pheomelanins · Allomelanin · Neuromelanin · Pyomelanins · Polyphenols · Tyrosine · Tyrosinase · DOPA · 5,6-Dihydroxyindole · 5,6-Dihydroxyindole-2-carboxylic acid · 5-S-CysteinylDopa · 1,8-Dihydroxynaphthalene · Homogentisic acid

Definition

“Melanins” is a generic term commonly used to define dark and insoluble pigments found in living organisms, including animals, plants, and microorganisms (fungi and bacteria), arising biosynthetically from the oxidative polymerization of L-tyrosine or other phenolic substrates. A recent classification of melanins includes the black-to-dark brown eumelanins and the reddish-brown sulfur-containing pheomelanins (in animals), neuromelanin (in catecholaminergic regions of the brain), allomelanins (in plants and fungi), and pyomelanin (in bacteria). Melanins display a peculiar set of physicochemical properties that have been implicated as underlying most of their biological roles including photoprotection, camouflage, and virulence, denoting per se a melanin-like pigment.

Overview

The origin of the term “Melanins” (from μέλας, black) is attributed to the Swedish chemist Berzelius (1840) with reference to the dark pigment found in eye membranes and was initially used to denote the major dark pigments present in surface structures of vertebrates, including man (Prota 1992; Riley 1997). Sometimes, however, the term has been used fairly indiscriminately to mean any dark pigment without specific biosynthetic or functional implications.

The basic classification of melanins is due to Nicolaus (1968), who divided these natural pigments into three main groups: eumelanins, pheomelanins, and allomelanins. The former two groups comprise animal pigments while the latter group refers to the broad collection of dark non-nitrogenous pigments of plant, fungal, and bacterial origin (Glagoleva et al. 2020).

Later, Prota proposed a more restrictive usage of the term “melanin” to include only those pigments that are formed intracellularly by the oxidation of L-tyrosine and related metabolites (Prota 1992), thus taking both the biogenetic origin from L-tyrosine and the metabolic activity of melanocytes and other pigment cells as key requisites for a pigment to be classified as a melanin.

Recently, as knowledge on melanin occurrence and distribution in nature has increased, an improved consensus definition and classification of melanins *sensu stricto* has been proposed, as *pigments of diverse structure and origin derived by the oxidation and polymerization of tyrosine in animals or phenolic compounds in lower organisms* (d’Ischia et al. 2013). This definition allows to set the modern classification of melanins into five main groups (Fig. 1):

Eumelanins (εὖ = good, true): *Black-to-brown insoluble subgroup of melanin pigments derived at least in part from the oxidative polymerization of L-DOPA via 5,6-dihydroxyindole intermediates.* Typical eumelanins are found in the skin, hair, and eyes of dark-complexioned phenotypes, as well as in bird feathers, amphibians, reptiles, fish (zebrafish is an established model for studies of melanoma), and cephalopod ink.

Pheomelanins (φαιος = gray): *Yellow-to-reddish brown, alkali-soluble, sulfur-containing subgroup of melanin pigments derived from the oxidation of cysteinyl-dopa precursors via benzothiazine and benzothiazole intermediates.* Typical pheomelanins include red human and mammalian hair and hen feather pigments (although red hair pigment is rarely pure pheomelanin).

Neuromelanins: *Dark pigments produced within neurons by the oxidation of dopamine and other catecholamine precursors.* The typical example of this class of melanins is the pigment from human *Substantia nigra*.

Allomelanins (ἄλλος = other): All other melanins like the dark non-nitrogenous phenolic pigments from plants and lower organisms, which cannot be classified as eumelanins, pheomelanins, or neuromelanins. Typical allomelanins are fungal melanins and the pigments found in some black seeds like black sesame.

Pyomelanin (πύον = pus): A eumelanin-like pigment produced by *Pseudomonas* and *Aspergillus fumigatus* in the presence of L-tyrosine via homogentisic acid (Schmaler-Ripcke et al. 2009).

It is worth noting that in several instances two or more different types of pigments are co-produced by the same organism. For example, pheomelanin in red hair and feathers is usually found mixed with eumelanin in variable proportions.

When seen from an evolutionary perspective, melanin distribution across the phylogenetic tree suggests that the appearance of nitrogen-containing units in melanin pigments marks the passage from lower organisms and plants to the animal kingdom. Moreover, the presence of a mutated phenotype with reddish sulfur-containing cysteine-derived melanin pigments, the pheomelanins, seems to be associated with higher levels of evolution (the red-haired phenotypes in man and mammals).

An evolutionarily preserved primitive role of melanin pigments is documented by their identification in various fossils (see e.g. Negro et al. 2018; Lindgren et al. 2015; Rossi et al. 2019). Melanin and melanosomes have been detected in diverse fossils leading to inferences about the

Melanins, Fig. 1 Modern classification of melanin pigments. The monomer precursors are highlighted in the boxes

adaptive coloration and behavior of extinct taxa (Vinther et al. 2016; Hu et al. 2018).

Evidence for non-integumentary melanin (extracutaneous, i.e., from internal tissues, excluding the eyes) in extant vertebrates and fossil amphibians (Dubey and Roulin 2014; McNamara et al. 2018) supported the possibility that these pigments played broader functions exceeding the mere integumentary coloration (Vinther 2015).

Records of melanin pigments in fossils include organosulfur-Zn complexes as indicators of pheomelanin in extant and fossil soft tissue of a three-million-year-old mammal species (*Apodemus atavus*) (Manning et al. 2019) and the presence of eumelanin in the soft tissue headcrest of the pterosaur *Tupandactylus imperator* (Pinheiro et al. 2019).

Basic Methodology

Animal melanins arise biosynthetically from the metabolic activity of highly specialized cells, the melanocytes, via the oxidative conversion of L-tyrosine catalyzed by the copper enzyme tyrosinase. The pathway leading to the synthesis and deposition of eumelanins involves the following key steps:

1. Tyrosinase-catalyzed conversion of L-tyrosine to DOPAquinone
2. Intramolecular cyclization of DOPAquinone and oxidation to DOPAchrome
3. Rearrangement/isomerization of DOPAchrome with/without decarboxylation to give 5,6-dihydroxyindole (DHI) and/or 5,6-dihydroxyindole-2-carboxylic acid (DHICA)

4. Oxidative polymerization of DHI and DHICA to eumelanin

Following mutation at *mc1r*, a critical gene for the eumelanin pathway, the formation of the dark pigments is partially inhibited and a switch occurs from eumelanin to pheomelanin synthesis following the intervention of L-cysteine.

Key steps in pheomelanin synthesis are:

1. Addition of L-cysteine to DOPAquinone to give 5-S-cysteinylDOPA as the main conjugation product
2. Oxidation of 5-S-cysteinylDOPA to its quinone followed by intramolecular cyclization to give dihydro-1,4-benzothiazine derivatives
3. Oxidation of dihydro-1,4-benzothiazine derivatives to give pheomelanin via partial isomerization to benzothiazole derivatives

In the dopaminergic neurons of *Substantia nigra pars compacta*, neuromelanin formation seems to proceed without enzymatic assistance due to a failure of the antioxidant defense system to control catecholamine autoxidation. This latter process involves the following steps:

1. Oxidation of dopamine to dopaminoquinone
2. Intramolecular cyclization of dopaminoquinone and oxidation to dopaminochrome
3. Isomerization of dopaminochrome to DHI
4. Oxidative polymerization of DHI to neuromelanin

The pathway represented by the above steps appears to be intermeshed with a pheomelanin-type reaction channel derived from the partial entrapment of dopaminoquinone by L-cysteine leading to give benzothiazine intermediates that are eventually incorporated into the neuromelanin polymer.

Allomelanin synthesis in plants may involve different phenolic substrates including catechol, caffeic, chlorogenic, protocatechuic, and gallic acids (Lyakh 1981; Bell and Wheeler 1986; Glagoleva et al. 2020). The biosynthetic process consists in the oxidative polymerization of the phenolic/catecholic substrates assisted by enzymes such as polyphenol oxidase.

Fungal melanins can be formed from gamma-glutaminy-3,4-dihydroxybenzene, L-DOPA, and 1,8-dihydroxynaphthalene. *Aspergillus fumigatus* can synthesize melanin-type pigments from 1,8-dihydroxynaphthalene, while *Serratia marcescens* (Trias et al. 1989) or the pathological fungus *Cryptococcus neoformans* (Feldmesser et al. 2000) can produce similar pigments from alternate pathways.

The biosynthetic pathway of bacterial pyromelanins starts from homogentisic acid, a metabolite deriving from L-tyrosine, involves the intermediate formation of the corresponding *p*-quinone derivative, and proceeds through an oxidative polymerization process.

A schematic outline of the biosynthetic pathways is reported in Fig. 2.

Key Research Findings

Production of melanin is now recognized as a universal adaptive behavior of living organisms to variable environmental conditions and cues. The presence of various types of melanins throughout the phylogenetic scale underscores the potential evolutionary importance of melanogenesis, which could be rooted in the peculiar physical and chemical characteristics of its products. Although the subject of multidisciplinary investigations since time immemorial, the biological roles of melanins are still a matter of debate. Besides photoprotection in human skin and exposed organs, accepted melanin functions include camouflage, antioxidant and free radical scavenger defense, UV dissipation, ionic conductor behavior, and de-toxication via binding of metals and xenobiotics.

At the lowest evolutionary levels, which may be of closer relevance to prebiotic processes, the ability to produce melanin from various phenolic substrates is typical of various microorganisms. Thus, the possible scenario of evolution of melanogenesis would include extracellular oxidative polymerization of phenolic compounds to active secretion of substrates and enzymes supporting this process, followed by a gradual adaptation to the intracellular control of the process and delivery of melanin to the surrounding.

Melanins, Fig. 2 Schematic outline of the biosynthesis of eumelanins, pheomelanins, neuromelanins, pyromelanins, and fungal melanins

In fungi, melanins are believed to offer protection from UV light and ionizing radiation as well as resistance to heat or cold (Wang and Casadevall 1994; Malo and Dadachova 2019). The ability of melanized fungi to survive high doses of ionizing radiation and the associated extreme environments is a particular example of radioresistance in which melanin provides not only physical resistance to ionizing radiation but also the ability to dynamically respond to such conditions. This latter can be related to the phenomenon of radiotropism, that is, the ability to grow toward a radiation source, as reported for melanized fungi such as *Aspergillus versicolor* and *Cladosporium cladosporioides* isolated from the Chernobyl reactor (Zhdanova et al. 1991). The growth of these strains toward radioactive particles and the capacity to adsorb them was observed to correlate with the degree of pigmentation.

In addition to protection from radiation, melanins in microbial organisms may serve as electron acceptors or carriers to produce energy under anaerobic conditions, may help maintain ion balance via electron exchange with insoluble compounds of iron (Menter and Willis 1997), and may be a factor of virulence in pathogenic microorganisms by lowering the vulnerability to the defense mechanisms of the hosts. In the case of eukaryotic microbial enzymes melanin

production is normally associated to modification of the cellular wall. Several reviews collect current knowledge about melanin roles and functions in low organisms (Tran-Ly et al. 2020).

Melanins, regardless of, and despite structural and biosynthetic differences, display a common set of physicochemical properties that can be taken as a useful criterion to classify a complex organic polymer as a melanin. These properties include, among others, (a) almost complete insolubility in water and organic solvents; (b) a black or dark coloration due to broadband, often featureless absorption spectra covering the entire UV-visible range; (c) an intrinsic paramagnetic character responsible for a broad stable EPR signal; (d) semiconductor-type electrical conductivity properties; (e) efficient non-radiative excited state deactivation; (f) a redox behavior associated with a marked antioxidant activity; and (g) a strong metal cation binding and drug affinity.

These and other properties have been recently reviewed in terms of the marked structural heterogeneity of melanins. Such a heterogeneity derives in part from the participation of different monomer units in the growing polymer backbone and in part from post-synthetic modifications, and accounts for a high level of chemical complexity stemming from various interrelated levels of structural disorder (d'Ischia et al. 2020).

Future Directions

Melanin pigmentation is an adaptive phenomenon widespread in living organisms from man to bacteria and extensively documented in fossil records. It occurred very early in all living organisms and that can be probably traced back to the earliest forms of life or even to the origin of life itself (Zhang et al. 2010; Glass et al. 2012). Melanin is a multifunctional polymer-like complex chemical system displaying the ability to absorb a wide range of radiations (Brenner and Hearing 2008; Liu et al. 2013), to serve as an antioxidant and radical scavenger (Ju et al. 2011), to chelate metals and bind organic compounds (Tran-Ly et al. 2020), and to transduce redox signals. Melanogenesis may thus have developed as a survival strategy for many organisms suffering extreme or unfavorable environmental conditions. Starting from these evidences, future perspectives will concern the exploitation of the properties of melanins to design a set of innovative and high-performing materials for applications in different fields.

Definition

A membrane is a fine structure that encloses the ► [cell](#) and separates the cytoplasm from the environment. In eukaryotic cells, membranes compartmentalize organelles to segregate processes and components.

Overview

The cell membrane is a thin bilayer (5–8 nm) of complex lipids embedded with proteins as depicted in the Fluid Mosaic Model. The bilayer is arranged so that the polar ends of the lipids form the outermost surface of the membrane while the nonpolar ends form the center of the membrane bilayer. ► [Bacteria](#) and ► [Eukarya](#) have membranes composed mainly of glycerol-ester lipids, whereas ► [Archaea](#) have membranes composed of glycerol-ether lipids. Archaeal lipids are based upon nonpolar isoprenoid side chains. The proteins of the membrane can be of two different types: transmembrane or integral membrane proteins, which are inserted into the ► [lipid bilayer](#) and in some cases bound to the lipids; and peripheral membrane proteins, which are usually attached by ionic bonding to the protruding portion of some integral membrane proteins.

Membrane structure and composition make them selectively permeable, allowing only certain substances to enter or leave the cell. Dissolved gases and lipid soluble molecules simply diffuse passively across the bilayer but all other molecules require carrier molecules to transport them through the membrane by active transport. In transport processes, cells use transport membrane proteins and metabolic energy to transport substances across the membrane against concentration gradients. Depending on the carrier protein, the energy is provided by proton-motive force, the hydrolysis of ATP, the breakdown of some other

high-energy compound, or other substance concentration gradients.

A number of functions associated with the internal membranes of eukaryotic organelles are carried out in bacteria by the cell membrane as well as some other functions of bacterial membranes including energy production, motility, ► [endospores](#) formation, binary fission, cell adhesion, cell signaling, and attachment point for cytoskeleton.

The ► [gram-negative bacteria](#) cell envelope contains an additional outer membrane, the lipopolysaccharide (LPS) layer, composed of phospholipids and lipopolysaccharides, which face the external environment.

Psychrophilic and psychrotolerant bacteria have different strategies to adapt to low temperature, one of which is the ability of the cell to modulate the fluidity of the membrane by altering the fatty acid composition by including high concentrations of lipids with unsaturated fatty acids in their membranes. Similarly, highly saturated fatty acids in the cell membrane of thermophiles maintain their integrity even at high temperatures. Hyperthermophilic Archaea have side chains of covalently bonded glycerol tetraethers forming a lipid monolayer that resist melting at the high temperatures at which they grow.

Some compounds can alter microbial cell membranes and are used to control bacterial infections.

The formation of membranes to separate the contents of the cell from the environment is considered an important event in the early steps of the origin of life.

Membrane Potential

David Deamer

Department of Chemistry, University of California, Santa Cruz, Santa Cruz, CA, USA

Keywords

Concentration gradient · Nernst equation · Polarization · Selective permeability

Synonyms

[Diffusion potential](#); [Nernst potential](#)

Definition

Membrane potential is the difference in electric potential produced across membranes by ionic ► [concentration gradients](#), if the membrane barrier contains channels that preferentially allow either cationic or anionic solutes to flow through. Membrane potential is measured in units of volts or millivolts.

Overview

Living cells today have evolved a variety of trans-membrane channel proteins that allow sodium or potassium ions to pass through the ► [lipid bilayer](#) barrier of membranes. Gradients of these ions are

produced and maintained by the action of ion transport enzymes that use ► [ATP](#) as an energy source. Potassium ions, carrying a positive charge, tend to diffuse down their concentration through the ion specific channel, while sodium and chloride ions cannot. As a result, the membrane becomes polarized, positive outside and negative inside, and the polarization is measured as a membrane potential. The voltage is described by the Nernst equation, a simplified form of which is:

$$V = 0.059 \log \left(\frac{C_o}{C_i} \right) \quad (1)$$

where C_o and C_i are the external and internal concentrations of an ion such as potassium. Typical gradients are approximately tenfold, and from the Nernst equation, a tenfold gradient produces a membrane potential of 0.059 V, or 59 mV.

Membrane potentials can also be produced by the active transport of protons. The electron transport systems of bacteria are capable of pumping 1,000-fold gradients of protons, equivalent to 180 mV. Mitochondria and ► [chloroplasts](#) are evolutionary descendents of bacteria and also pump protons. According to the chemiosmotic theory, a membrane potential of protons is the essential energy source for ATP synthesis. The relation to early forms of life is that at some point the membranes of primitive bacteria were able to generate and maintain a membrane potential, so that chemiosmotic ATP synthesis could occur. How this could happen remains an open question for research on the origin of life.

Mars exploration rovers

Definition

Mars Exploration Rover (MER) is a ► [NASA](#) mission composed of two identical robot geologists, SPIRIT and OPPORTUNITY, which were launched separately in June and July 2003, respectively. After their successful landing on the surface of ► [Mars](#) in January 2004, in areas near the equator, they started exploring their landing sites, searching for clues of past water activity on Mars. Both Mars Exploration Rovers were designed to last 90 ► [sol](#) (a Martian day = 1.027491 Earth days). SPIRIT has been operating for 6 years 2 months and 25 days; it drove 7.73 km. OPPORTUNITY is still functioning more than 11 years after landing and with an odometry of more 42 km.

Overview

The MER mission is part of the Mars exploration program that NASA has conducted regularly to decipher the history of this planet, to find whether life ever existed there, and to prepare a future human visit.

After the previous missions, both in orbit (► [Mars Global Surveyor](#) [MGS], ► [Mars Odyssey](#)) and on the surface of Mars (Viking 1 & 2, ► [Mars Pathfinder](#)), it appeared likely that liquid water had been present in the past on the surface of Mars. Then, the questions were when in the history of Mars, and how long were those periods of liquid water.

The MER mission consisted in sending to Mars two identical robotic rovers to explore areas of Mars that were selected because they presented likely indications of past activity of water. These landing sites were chosen among areas that satisfied the engineering constraints for a safe landing (Fig. 1). One is within the flat-floored Gusev crater (14.57°S, 175.47°E) at the end of the large valley Ma'adim Vallis, suggesting that the materials inside were deposited in a crater lake. The second one is in Meridiani Planum (354.47 E, 1.95°S), composed of basaltic sand and sparse outcroppings, where the identification of coarse-grained hematite in MGS Thermal Emission Spectrometer (TES) spectra and the geologic setting from Thermal Emission Imaging System (THEMIS) data could arguably indicate the influence of liquid water.

Within just a few months of arriving on Mars, both Spirit and Opportunity fulfilled their mission objectives and discovered evidence that large quantities of water used to be on the surface of Mars. Spirit discovered hints that water had acted on a ► [rock](#) called Humphrey, while Opportunity

M

MER, Spirit, and Opportunity (Mars),
Fig. 1 Location of the
landing sites (Credit:
NASA/JPL)

found layers of sedimentary rock that would have been formed by deposits in water. Both rovers continued to find additional evidence for the presence of water.

Over the course of their mission on the surface of Mars, both rovers traveled several kilometers. Spirit climbed a small mountain, and Opportunity crawled into a large crater to sample the walls for evidence of past water. And both rovers continued to perform quite well, for many years beyond their originally estimated life spans. In total, Spirit traveled 7.76 km and survived three martian winters, while OPPORTUNITY covered more than 42 km, and is still progressing, and has survived six martian winters.

Basic Methodology

The rovers and their operational capacities were designed according to the scientific objectives of the mission, which were defined following the general motto “Follow the water.” Its main objectives are to search for and characterize a variety of rocks and soils, in particular, samples that could have minerals deposited by water-related processes and to determine their distribution in the surroundings of the landing sites in order to determine what geologic processes have shaped the local terrain and influenced the chemistry. The rovers should also search for geological clues to the environmental conditions that existed when liquid water was present, in order to assess whether those environments were conducive to life.

Consequently, each rover is equipped with a suite of science instruments to read the geologic record at each site, to investigate what role water played there, and to determine how suitable the conditions would have been for life.

The scientific instrument suite consists of the following:

1. A panoramic Camera (PANCAM) mounted 1.5 m high on the Pancam Mast Assembly, for characterizing the local terrains; it is a stereo pair with eight possible filters for each eye.

2. A miniature infrared spectrometer for the thermal emission (miniTES) whose mirror is also mounted on the mast near the PANCAM, to determine the mineral composition of rocks and soil.
3. A microscope camera imager (MI) at the end of the robotic arm to obtain close-up high-resolution macroscopic images of target rocks and soil.
4. An alpha particle and X-ray fluorescence Spectrometer (APXS), for close-up analysis of the abundances of elements that make up rocks and soils.
5. A Mössbauer spectrometer (MB) for close-up investigations of the mineralogy of iron-bearing rocks and soils.
6. A rock abrasion tool (RAT) for removing dusty and weathered rock surfaces and exposing fresh material for examination by the suite of instruments.
7. Three sets of magnets for collecting magnetic dust particles. The particles are analyzed by the Mössbauer spectrometer and x-ray spectrometer to help determine the ratio of magnetic particles to nonmagnetic particles and the composition of magnetic material.

The two rovers are identical six-wheeled, solar-powered robots with a mass of 180 kg (Fig. 2). Each Mars rover communicates with Earth using antennas that transmit information to either Deep Space Network (DSN) antennas on Earth or to any spacecraft orbiting Mars, which in turn relays the information to land-based stations on Earth.

To move autonomously on the uneven surface of Mars, the rovers use three pairs of monochromatic cameras and navigation software which identifies obstacles; the pairs of cameras allow for 3D vision and are located at the front and at the rear under the solar panel deck, and on top of the mast to allow for a larger view used for planning the displacements.

They are also equipped with a robotic arm called the instrument deployment device (IDD), which holds a grinding tool (RAT) and in situ instruments (MI, APXS, and MB).

MER, Spirit, and Opportunity (Mars), Fig. 2 Description of the main elements of the MER rover

Story Board of the Mission

The main events that marked the exploration of either rover are listed below:

- Landings occurred on January 4 for SPIRIT and on January 25, 2004, for OPPORTUNITY. At first, the Gusev area appeared as dry and devoid of past water activity, similar to Mars Pathfinder or Viking landing sites. On the other side of the planet, OPPORTUNITY found itself in the middle of a small depression caused by impact, the Eagle crater, which revealed rock outcrops showing layering and composition that could be sediments deposited by water (Fig. 3).
- On March 11, 2004, Spirit reached Bonneville crater hoping for a view of underlying bedrock, but none was visible and it was decided to continue toward the Columbia hills.
- On April 30, 2004, OPPORTUNITY arrived at Endurance crater and started to explore its inner slope until it exited on September 22 (Fig. 4).
- On June 15, 2004, SPIRIT arrived at the foot of the Columbia Hills and started observing very different rocks that suggested that they had undergone water alteration (Fig. 5). Then, while climbing, several dust devils were observed, some of them cleaning the solar panels, thus allowing for a supplement of electric power.
- On August 21, 2005, SPIRIT reached the summit of Husband Hill. It then went on downhill, making more analyses of the different outcrops and soils.
- On February 7, 2006, SPIRIT reached the semicircular rock formation known as Home Plate. It is a layered rock outcrop, and it is

MER, Spirit, and Opportunity (Mars), Fig. 3 Magnified view of a portion of outcrop rock seen in Eagle crater, which is interpreted as sediments that were laid down in flowing water (Credit: NASA/JPL)

MER, Spirit, and Opportunity (Mars), Fig. 4 View of the “burncliff” formation within Endurance crater that shows stratification that was analyzed to decipher the emplacement history (Credit: NASA/JPL)

thought that its rocks are explosive volcanic deposits, though other possibilities exist, including impact deposits or wind/waterborne sediment.

- OPPORTUNITY arrived at Victoria crater on September 27, 2006, and started to observe from around its rim. After a large dust storm faded away, OPPORTUNITY entered Victoria crater in September 2007 and analyzed the rock layers until exiting on August 29, 2008.
- OPPORTUNITY continued its way toward the very large Endeavour crater 12 km further

south; it is progressing through sand dunes fields, making detours to avoid the most risky paths.

- Since May 2009, SPIRIT had been stopped with its wheels sunk in very loose sand on the west of Home Plate. After unsuccessful attempts to extricate the rover from this trap, NASA redefined the robot mission as a stationary research platform.
- End of March 2010, SPIRIT went into hibernation at her location on the west side of Home Plate due to low electric power production

during Martian winter. Next Martian spring started in November 2010. When Martian spring and then summer passed without receiving any signal from SPIRIT, the enduring rover mission had been declared over in May 2011.

- On its way to the large crater Endeavour, OPPORTUNITY stopped on December 16, 2010, by a fresh crater named Santa Maria, and it stayed there during conjunction and analyzed a piece of outcrop in which the MRO CRISM instrument had identified kieserite ($\text{MgSO}_4 \cdot \text{H}_2\text{O}$), a hydrated mineral not seen before by OPPORTUNITY.
- OPPORTUNITY entered the western rim of Endeavour crater on August 9 after a total drive of ~ 33.5 km. This crater is a Noachian period impact, and the largest visited by the rover with a diameter of about 22 km.
- In a thorough examination of a part of the western rim called Cape York, OPPORTUNITY spent almost 2 years including its fifth winter campaign. It made a stratigraphy analysis of this ridged hill.
- From May 2012 to April 2013, the robot field geologist has been on an excursion, traveling back in geologic time on Matijevic Hill, located along the inboard side of the Cape York segment of Endeavour's rim. It has found mystery "newberries," and veins of

gypsum, large and small, running through bedrock and ancient soft rocks, the residual signs of clay minerals of which OPPORTUNITY observations support the identification of smectite as derived from MRO CRISM data. These findings bring solid evidence that once, long, long ago, lots of flowing water, kind of like water on Earth, created a habitat there suitable for the emergence of life.

- OPPORTUNITY continued then its route along the western rim of Endeavour's crater toward Solander point where it has found a larger set of strata and stayed during its sixth Martian winter (Fig. 6).
- In the course of its exploration along the western rim of Endeavour, OPPORTUNITY went up and down through hills, craters and valleys looking for more hints of the liquid water history of Mars.
- At some point in 2015, it's flash memory couldn't anymore keep the files over sleeping times and the onboard software had to be

MER, Spirit, and Opportunity (Mars), Fig. 5 False-color image taken by the panoramic camera on the Mars Exploration Rover Spirit shows the rock dubbed "Pot of Gold" located near the base of the Columbia Hills in Gusev Crater (Credit: NASA/JPL)

MER, Spirit, and Opportunity (Mars), Fig. 6 This picture shows one of the light-tone, flat Whitewater Lake rocks that are harboring the smectite clay minerals the MER team came looking for at Endeavour Crater. The rover saw these flat, light-tone rocks all around her in mid-November as she completed her survey Matijevic Hill. The Pancam team processed this picture in false color to better show the dark coating or rind that immediately set these stones apart (Credit: NASA/JPL-Caltech/Cornell/UA)

modified so that the rover could continue its operational capabilities.

- In 2016, while looking down the Marathon Valley, OPPORTUNITY recorded an image of a Martian dust devil (Fig. 7); such phenom-

MER, Spirit, and Opportunity (Mars), Fig. 7 From the height of the Marathon Valley, OPPORTUNITY caught this picture of a dust devil twirling within Endeavour crater. (Credit: NASA/JPL-Caltech/MSSS)

ena have been commonly observed by SPIRIT in the Gusev crater, but were rare over Meridiani planum.

- In early June 2018, while in the flank of Perseverance Valley, one of the most intense ever observed dust storm covered a large part of the Martian surface. It has effectively blocked the sunlight preventing OPPORTUNITY of receiving enough energy and sent the rover into hibernation on sol 5111 (June 10, 2018); on this date OPPORTUNITY had sent his last message. After this massive storm had last until August, many attempts were made to recover any contact with the rover until February 13, 2019, when NASA declared that the mission had come to an end.

Beyond its exceptional duration, OPPORTUNITY had traveled a record distance of 45.16 km (Fig. 8), transmitted 217,594 images of Mars, exposed the surfaces of 52 rocks to reveal fresh mineral surfaces for analysis and cleared 72 additional targets with a brush to prepare them for inspection with spectrometers and a microscopic imager.

MER, Spirit, and Opportunity (Mars), Fig. 8 OPPORTUNITY lifetime progress year after year; Washington DC is superimposed for size comparison (credit: James919 — Travail personnel, CC BY-SA 4.0)

Key Research Findings

Signs of the past presence of water indicated that there has been liquid water in large quantities and for long periods of time. Little spherules that contain ► **hematite** (Fe_2O_3), called “blueberries,” have been found by OPPORTUNITY everywhere on the Meridiani Planum; they are considered as an indicator of a long presence of liquid water. There have been also other signs in the fine outcrop layering, or in the presence of vugs (small to medium-sized cavities inside rocks) in the bedrock, and with the identification of ► **Jarosite**, a basic hydrous sulfate of potassium and iron. In the Columbia Hills, Spirit found also very typical minerals, in particular, pure silica, and also ► **goethite** ($\text{FeO}(\text{OH})$), and for the first time some long-sought-after carbonate.

All those observations indicate that the past environment at these locations was wet, possibly favorable to life. Furthermore, the variety of such places in which life could have found a way to emerge demonstrates that there are more places on Mars where conditions were good for a long period of time than previously imagined.

The atmospheric temperature variations through several Martian years have been recorded; density and composition of atmospheric dust and water ice ► **aerosols**, together with the obscuring of solar light, have been observed by both rovers. Numerous dust devils were seen during spring and at the beginning of summer.

Core · Exosphere · NASA mission Mariner 10 · NASA mission Messenger

Definition

Mercury is the innermost ► [planet](#) and the smallest of the four ► [terrestrial planets](#). It is the only terrestrial planet except Earth to have a global magnetic field. Mercury shows the most extreme surface temperature variations of all terrestrial planets. The average surface temperature is 442.5 K, with dayside temperatures up to 700 K and nightside temperatures down to 80 K. Mercury has a tenuous exosphere containing hydrogen, helium, oxygen, sodium, calcium, and potassium. This exosphere

is not stable – atoms are continuously lost and replenished from a variety of sources.

Overview

So far, only two spacecrafts have visited Mercury. The NASA mission Mariner 10 made 3 flybys in 1974 and 1975. The NASA mission MESSENGER made three flybys between 2007 and 2009 and has entered orbit around the planet in March 2011. The ESA mission BepiColombo will observe the planet from orbit starting 2019. Observing Mercury from ► [Earth](#) is challenging. While it is bright, ranging from –2.3 to 5.7 in apparent magnitude, the greatest angular separation from the Sun is only 28.3°. Since Mercury is normally lost in the glare of the Sun, unless there is a solar eclipse, Mercury can only be viewed in morning or evening twilight.

With a radius of 2,439.7 km, Mercury is the smallest of the terrestrial planets and its evolution and formation can provide important clues to the formation of planetary systems in general.

With 5.427 g/cm³, Mercury has the second highest density of all terrestrial planets (Earth: 5.515 g/cm³). It has the highest metal-to-silica ratio of all planets or satellites. The surface mineralogy seems to be dominated by plagioclase. The ► [magnetic field](#) of Mercury has about 1.1% of the strength of the Earth's magnetic field. Observations by the NASA spacecrafts Mariner 10 and MESSENGER have indicated that the strength and shape of the magnetic field are stable. The high density and the magnetic field combined lead to the assumption that Mercury has a large iron core occupying about 42% of its volume, compared to 17% for Earth. There are several competing theories for the origin of this large core during the formation of Mercury, ranging from a giant impact that striped the planet of its crust to inhomogeneities in the early solar nebular leading to an enrichment of proto-Mercury in iron.

Mercury has a mean heliocentric distance of 0.3871 AU. One orbit around the Sun takes 87.969 days; in this time, the planet performs 1.5 rotations. This 3:2 spin-orbit coupling has been explained by Giuseppe Colombo. Given the eccentricity of Mercury's orbit, the 3:2 coupling

minimizes the tidal torque (see tides) on the planet during perihelion passage.

The exosphere of Mercury is formed by thermal desorption and sputtering of surface material, as well as captured solar wind particles. The NASA MESSENGER spacecraft detected indications for water in the exosphere, most likely formed from solar hydrogen and oxygen sputtered off the planet's surface.

Radar observation from Earth show bright regions close to Mercury's poles. This could be an indication for water ice deposits in permanently shadowed craters.

Meridiani (Mars)

Ralf Jaumann
German Aerospace Center (DLR), Institute of Planetary Research, Berlin, Germany

Definition

Meridiani Planum is an extended plain on ► [Mars](#) centered at 357.5°E/0.2°N in the western part of

an ► [albedo feature](#) called Sinus Meridiani. Meridiani Planum was the landing site of the ► [Mars Exploration Rover Opportunity \(MER\)](#) in 2004. In Meridiani Planum cross-bedded sedimentary rocks are exposed that contain crystalline ► [hematite](#) (Fe₂O₃) and sulfate-rich ► [minerals](#) such as ► [jarosite](#). The presence of the latter mineral indicates an acid and saline environment and a soil saturated with liquid water during a considerable period of time. Airy-0, a small crater of 0.5 km in diameter at 0°E/5.1°S, defines the prime meridian of Mars. It is located within the larger (40 km) crater Airy in southern Meridiani Planum.

Mesophile

Felipe Gomez
Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Madrid, Spain

Definition

The term mesophile is mainly applied to ► [micro-organisms](#), and it refers to microbes whose optimal development temperatures are moderate, ranging from 15 °C to 45 °C. They are probably the most abundant and conspicuous group of microbes and their habitats are widely distributed, from soils to water to animal niches. Most of the pathogens for humans (bacteria and viruses) belong to this group.

Mesosphere

Sébastien Lebonnois
Laboratoire de Météorologie Dynamique
(LMD/IPSL), Sorbonne Université, CNRS, Paris,
France

Definition

In this region, as in the stratosphere (located below when existing), the dominant mode of energy transfer is radiation, with a balance between the energy absorbed from the stellar irradiation by gaseous components and particles when present, and the energy reemitted by these components at infrared wavelengths. This balance in these regions is characterized by local thermodynamic equilibrium, which means that the energy distributions of the molecules are in equilibrium and follow the Boltzmann distribution.

The mesosphere is characterized by a temperature that is either constant or decreasing with altitude. In Venus and Mars, the mesosphere is mostly isothermal and located immediately above the tropopause.

The upper boundary of the mesosphere is called the mesopause (at roughly 85 km altitude for the Earth). The thermosphere is the region above the mesopause.

Space mission · NASA discovery program · Planet Mercury · Evolution of the Solar System

Definition

MESSENGER (MERcury Surface, Space Environment, GEOchemistry, and Ranging) is a NASA (Discovery class) space mission which flew by Mercury three times in 2008/2009 before going in an orbit around our innermost planet in March 2011. It stayed in orbit for over 4 years before it intentionally crashed on the surface on 30 April 2015. Until that MESSENGER orbited Mercury more than 4100 times, its camera system took more than 290,000 images, and its instruments have made many unique and sometimes also surprising measurements which largely increased our knowledge about Mercury.

History

The spacecraft was designed and built by the Johns Hopkins University Applied Physics Laboratory – with contributions from research institutions and companies around the world (McNutt et al. 2006; Solomon et al. 2001). The spacecraft's graphite composite structure was integrated with a low-mass propulsion system. The spacecraft was protected behind a 2.5-meter by 2-meter sunshade to keep temperatures low and enabling the spacecraft and instruments to operate in the harsh environment around Mercury. The spacecraft was launched aboard a Delta II rocket on 3 August 2004. The journey took more than six and a half years. MESSENGER used six gravity-assists one at Earth, two at Venus, and three at Mercury

before it could be inserted into orbit around Mercury.

During its three Mercury flybys, it provided first close-up looks of the surface of Mercury in more than 30 years (after NASA's Mariner 10 spacecraft flew by Mercury in 1974/1975). At that time, MESSENGER photographed also areas of Mercury not imaged during the Mariner 10 encounters.

The science goal of MESSENGER was to contribute to the understanding of Mercury, the smallest, densest, and least explored of the terrestrial planets.

The science payload onboard MESSENGER consist of the following instruments:

- **Mercury Dual Imaging System (MDIS)** – detailed color and monochrome images of Mercury's surface.
- **Gamma-Ray and Neutron Spectrometer (GRNS)** – element composition of the planet including the polar areas.
- **X-Ray Spectrometer (XRS)** – elements in Mercury's crust.
- **Magnetometer (MAG)** – Mercury's magnetic field investigations.
- **Mercury Atmospheric and Surface Composition Spectrometer (MASCS)** – atmospheric species and surface composition.
- **Energetic Particle and Plasma Spectrometer (EPPS)** – charged particles in Mercury's magnetosphere.
- **Mercury Laser Altimeter (MLA)** – topography of surface features; determines whether Mercury has a fluid core.
- **Radio Science uses Doppler tracking** – Mercury's mass distribution.

Measurements performed by MESSENGER have shown that volcanism has played a critical role in shaping Mercury's surface. Mercury is abundant in volatile elements, which was not expected for such a small planet and has changed our view about the formation and early history of the innermost planet. Results have further shown that Mercury contracted by as much as 7 km in radius. MESSENGER discovered a geologic landform called Hollows. These shallow,

irregular depressions are some of the brightest and youngest features on the surface of Mercury and have not yet been seen on other planets. It could be demonstrated that Mercury's polar regions very likely host water ice. Illumination models of these regions derived from the topography show that the radar-bright deposits measured from ground and indicate the presence of water are located in regions of permanent shadow. The existence of an Earth like magnetic field, but 100 times weaker, was confirmed. However, in addition, it was found that magnetic field is offset along the planetary spin axis by about 400 km to the north. Mercury's magnetosphere is highly dynamic because of the weak magnetic field and proximity to the Sun. The solar wind interacts with the magnetosphere and generates waves in particles and fields, reconnection of interplanetary and planetary magnetic field lines. MESSENGER detected electrons which seem an almost permanent part of Mercury's magnetosphere. Mercury's tenuous atmosphere scatters sunlight, and the emission brightness is proportional to its content (Solomon et al. 2018).

More information about the mission and images of the spacecraft and the instruments can be found in Solomon et al. (2018) and on the JHU/APL website (Johns Hopkins Applied Physics Lab (1999–2016)).

Metabolic Diversity

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Madrid, Spain

Definition

Metabolic diversity mainly refers to the different metabolic strategies that organisms have evolved to obtain energy. Metabolic pathways evolved among prokaryotes before eukaryotes arose as the result of their interaction and coevolution with changing physicochemical environmental conditions. Metabolic diversity is life's evolutive response enabling it to adapt to and use all available energy and organic and inorganic matter sources. Life, as we know it, follows common nutritional patterns that can be subdivided depending on energy or carbon requirements. Organisms can be classified according to their energy requirements as phototrophs, if energy comes from solar radiation, or chemotrophs, if the energy source is inorganic (► [chemolithotroph](#)) or organic (► [chemoorganotroph](#)) reduced compounds. According to the mechanism used, they can be classified as photosynthetic (oxygenic and anoxygenic), respirers (aerobic and anaerobic), and fermentors. Depending on the carbon source, organisms can be autotrophs or self-feeders, if carbon is fixed from CO₂ by the organisms, or heterotrophs or consumers, if the carbon source is already existing organic matter. Combining energy and carbon sources, organisms can be classified

into four groups: photoautotrophs (green plants, algae, and cyanobacteria), photoheterotrophs (some ► [Bacteria](#)), chemoautotrophs (some *Bacteria* and ► [Archaea](#), such as methanogens), and chemoheterotrophs (animals, fungi, protists, and most bacteria). Due to this adaptative response, metabolic diversity has tremendous astrobiological implications since such wide diversity could cover life's adaptation to other planetary conditions, especially the photoautotrophy or chemolithoautotrophy. An interesting property of some microorganisms is their metabolic versatility, which enables them to select their metabolic mode according to environmental conditions. The most versatile microorganisms known so far are the purple nonsulfur bacteria, a group of anoxygenic photosynthetic microorganisms that in the absence of light can employ aerobic and ► [anaerobic respiration](#) and ► [fermentation](#).

Definition

Metabolism is the collection of chemical reactions that define a living organism and allow it to make its components and obtain the energy required for staying alive.

History

Recognition that the processes occurring in a living organism are fundamentally chemical reactions came progressively with the decline in *vitalism* in the nineteenth century. The discovery of cell-free fermentation by Eduard Buchner sounded the death knell of vitalism and the beginning of the

unraveling of the major metabolic pathways that constitute metabolism. This process began with the understanding of ► [fermentation](#) and ► [glycolysis](#), and by the end of the 1950s, virtually all the major pathways were known.

Overview

Although a living organism is identified and recognized by its physical appearance and hence by its structure, its status as living is defined by its chemistry and thus by its *metabolism*. This is a network of reactions that is responsible for synthesizing all of the molecules needed for the organism to survive, apart from those directly available from its environment, and for disposing of molecules that are harmful or no longer required. The entire network consists of thousands of connected reactions, and as many of these need to be maintained far from equilibrium, all organisms require and consume energy.

To a first approximation, the metabolism of all organisms is the same, but there are important differences that depend on whether it is *aerobic*, requiring ► [dioxygen](#) as the ultimate electron acceptor, or *anaerobic*, which can be *facultative*, with dioxygen tolerated, or *obligate*, with dioxygen completely avoided. Some organisms, including plants and some bacteria and archaea, are ► [autotrophs](#) that produce organic compounds from inorganic precursors (CO₂ and carbonates being considered inorganic), whereas others, including all animals, fungi, and some bacteria and archaea, are *heterotrophs*, depending on other organisms as primary sources of organic materials. Aerobes use dioxygen as their primary source of oxidizing power, but anaerobes also need oxidizing precursors, such as sulfates, and can obtain oxygen from these. Heterotrophs use organic compounds ingested as food as their primary source of reducing power, but autotrophs do not require organic food. As they exist in an oxidizing environment, they cannot use inorganic reducing agents but depend on ► [photosynthesis](#) for reducing power.

Oxidation and reduction inevitably conflict with one another, and so metabolism is only

possible with a very high degree of *regulation*, preventing the terminal oxidizing and reducing agents from reacting directly with one another and similarly allowing synthesis (► *anabolism*) and degradation (► *catabolism*) to proceed without interference. Essentially no reactions must occur without *catalysis*, therefore, and the catalysts should be highly specific. With no thermodynamic prohibition of unwanted reactions, they can only be avoided by the absence of active catalysts, which is achieved by ► *enzyme* regulation and to some degree by *compartmentation* (Ginger et al. 2010), with physical barriers separating reactions that might conflict with one another: a cell is not just a bag of catalysts.

Only proteins (and to a much more limited extent RNA) can provide the necessary specificity that allows efficient catalytic activity in very mild conditions, and virtually all the catalysts of metabolism are protein-based *enzymes*. These cannot be harvested by an organism from its environment, but must be synthesized by the organism itself. Thus, although enzymes are conventionally regarded as different from *metabolites*, the chemical intermediates of metabolism, there is no fundamental distinction between them, both being produced internally from the same precursors, used internally, and broken down to the same end products.

During the course of evolution, several mechanisms have appeared that allow fine regulation of metabolism, such as *allosteric* and *cooperative* interaction of effectors with appropriate enzymes, chemical modification of enzymes (*metabolic cascades*), and compartmentation. Although cyclic pathways, such as the tricarboxylate (Krebs) cycle, have sometimes been claimed to be too complex to be the result of natural selection, a convincing analysis of the steps that could produce such a cycle has been given (Meléndez-Hevia et al. 1996).

Metabolism, Prebiotic

Harold Morowitz

George Mason University, Fairfax, VA, USA

Definition

Metabolism in contemporary biology and biochemistry refers to the aggregate of chemical transformations taking place in living organisms or in ecosystems. It consists of ► *anabolism*, the buildup of compounds, catabolism, the breakdown of compounds, and the alteration of compounds for energy transformation or usage. The word itself comes from Hellenic Greek, where it refers to change.

Overview

The contemporary usage seems to go back to the 1870s where it occurs in physiology books in the

sense of chemical change. In present day ecological systems, the overall metabolic activity consists of the incorporation of carbon, hydrogen, nitrogen, phosphorous, and sulfur driven by photosynthesis or chemosynthesis, the transformation of the inputs into metabolites, the buildup of these small molecules into macromolecules and other cell structures; and, ultimately, loss due to ► [respiration](#), predation, and decay. There are common features of metabolism across all taxa: the same amino acids, the same sugars, the same ► [nucleotides](#), and the same cofactors are used. These are matched even to the level of ► [chirality](#) and the universality of the ► [genetic code](#). Many of these intertaxonomic features were gathered together in the 1950s by Donald E. Nicholson in a chart of intermediary metabolism. This material was organized and codified in 1970, in the book “*An Introduction to Metabolic Pathways*” by S. Dagley and Donald E. Nicholson. What is striking is the universality of adenosine triphosphate and its hydrolysis in bioenergy transfer processes, the universality of macromolecule synthesis, and the universality of the citric acid cycle in both energy utilization and anabolism. All anabolism comes from five compounds in the citric acid cycle and the anaplerotic loop. A number of cofactors are essential and are either synthesized or obtained as vitamins. The enormous overlap in all metabolisms indicates it is a rare accident, it is the best solution to biochemistry, or it is the only solution to biochemistry.

The overlap of metabolic intermediates is a necessity for trophic ecology, for otherwise the predator or grazer would find its food indigestible or unusable. The universality question can potentially be answered by experimental astrobiology or a theory of living systems subject to experimental test. In any case, metabolism may be regarded as a feature of an organism or an ecosystem. Indeed, the failure to grow many of the microbes of an ecosystem in pure culture suggests difficulties in defining species metabolism and questions regarding the meaning of species at the microbial level.

Energy for metabolism is derived from mineral energy sources in the environment, photoautotrophy, or oxidative heterotrophy. Biogenesis

would require one of the first two. All metabolisms require the flow of energy from a high quantum-size source to a low quantum-size sink, making metabolism consistent with the laws of thermodynamics. Complete genome sequencing allows the construction of the metabolic chart in toto, since almost all reactions require enzymes that are encoded in the genome. This has led to a common autotrophic metabolic chart, most reactions of which are universal, again suggesting universal laws of metabolism.

One way to search for microbial life on other astronomical objects is to search for core molecules of metabolism. The total absence of such molecules would indicate no life or a life so metabolically different from terrestrial life that a reframing of the question of what life is might be required. For example, it is extremely unlikely that organisms metabolically different from those on Earth could be pathogenic. In any case, the full consequence of cross-contamination of spatial bodies should be viewed in terms of metabolism.

The laws of metabolism are a necessary feature of the laws of life on Earth and must form a central feature of astrobiology.

Metabolism, Secondary

Juli Peretó
Institut Cavanilles de Biodiversitat i Biologia
Evolutiva, Universitat de València, València,
Spain

Definition

Secondary ► [metabolism](#) is the subset of metabolic networks not directly involved in the

production of the essential cell components and, thus, not playing any part in cell growth and development. Secondary metabolites include chemical species with ecological functions (e.g., antibiotics) and are more or less elaborated derivatives from metabolites involved in central pathways. Thus, secondary metabolism occupies a peripheral position in metabolic networks.

Metatranscriptomics · Microbial diversity

Synonyms

[Community genome](#); [Environmental genome](#);
[Population genome](#)

Definition

The metagenome is the genetic content of a biological community. The term is mainly applied to microbial communities which can be somehow considered as a whole entity and, consequently, treated and studied as a single “meta-organism” with a single ► [genome](#). It can also be applied to subpopulations like a viral population isolated from a whole microbial community. In such case, it is called the ► [metavirome](#) (the genome

of the virome). The term “meta” comes from Greek and means “next to” or “related to.”

History

Phylogenetic studies with the DNA ► [sequence](#) of environmental rRNA genes revealed that most of the microbial diversity (up to 99 %) remained unexplored when only culturing techniques were applied. This was one of the main conclusions after the pioneering work conducted by Norman R. Pace and colleagues, who used the amplification technique called ► [polymerase chain reaction](#) to explore the diversity of ribosomal RNA sequences (Lane et al. [1985](#); Pace et al. [1985](#)). It was Jo Handelsman who in 1998 first suggested the term “metagenomics” for naming the idea that a set of ► [gene](#) sequences obtained from environmental samples could be analyzed as if they came from a single genome (Handelsman et al. [1998](#)). Since then many works have been reported where the whole genetic content of a microbial community (the metagenome) has been used either for gene sequencing and screening for novel enzymatic activities (Healy et al. [1995](#)), or for whole genome DNA sequencing (Tyson et al. [2004](#); Venter et al. [2004](#)).

Overview

The exploration of metagenomes has been tightly bound to the improvement and development of new cloning and amplification strategies and sequencing techniques, as well as advances in bioinformatics for sequence analysis. From the analysis of metagenomes, important information can be obtained about microbial and metabolic diversity as well as the versatility of natural populations. Some applications include: environmental monitoring either to follow the effect of pollutants or bioremediation technologies; monitoring of industrial processes conducted by microbial consortia; gene inventory of a microbial community either for the search of new enzymatic activities (Zhang et al. [2009](#)) or to explore the potential metabolic networks in the

community; sequencing single genomes from uncultivable microorganisms (Tyson et al. 2004); exploring potential pathogens in the microbial flora of humans and animals (Sommer et al. 2009); exploring the genetic wealth of environmental viruses from extreme environments (López-Bueno et al. 2009); exploration of the preferential gene expression in extremophilic communities for astrobiology purposes (Parro et al. 2007).

Metal Compounds in Circumstellar Envelopes

William M. Irvine

Department of Astronomy, University of Massachusetts, Amherst, MA, USA

Definition

A number of metal (in the chemical sense, rather than the astronomical sense in which all elements heavier than He are labeled “metals”) cyanides, isocyanides, oxides, chlorides, fluorides, and hydrides have been found by radio astronomers in the circumstellar envelopes of evolved stars, predominantly in carbon-rich stars (see ► [Molecules in Space](#) and ► [Circumstellar Chemistry](#)). The observed metals include Fe, K, Mg, Na, Al, Ca, and Ti.

History

The first metal-bearing species NaCl, KCl, AlCl, and AlF were detected by Cernicharo and Guélin in 1987 toward CW Leo. Subsequent detections have included FeCN (Zack et al. 2011), KCN (Pulliam et al. 2010), HMgNC (Cabezas et al. 2013), TiO, TiO₂, and CaNC (Cernicharo et al. (2019). In the ► [interstellar medium](#), as opposed to the circumstellar environment, metals in the

chemical sense are mostly incorporated into the ► [interstellar dust](#) grains.

Metallicity

Nikos Prantzos
Institut d’Astrophysique de Paris, Paris, France

Definition

Metallicity specifies the relative amount of elements heavier than helium (collectively called *metals* by astronomers) in a star, galaxy, or some part of the interstellar medium. The metallicity of the Sun is $Z_{\odot} = 1.5\%$ by mass. The most metal rich ► [stars](#) in the inner Galaxy have two or three times that figure, whereas the most metal poor halo stars of the Milky Way have metallicities as

low as $0.0001 Z_{\odot}$. Usually, the abundance of some key element (like Fe or O) is used as a proxy for metallicity. Host stars of extrasolar giant planets (observed in the solar neighborhood) are more metallic than non-planet hosting stars.

Metamorphic Rock

Jean-Emmanuel Martelat
Université Claude Bernard Lyon 1, Grenoble, France

Keywords

Metamorphic facies · Mineral assemblages · Protolith · Rock texture

Definition

A metamorphic rock forms when igneous, sedimentary, or older metamorphic rocks are subjected to heat, pressure, and strain that result in changes of their texture and mineral assemblage. The new texture, commonly characterized by aligned mineral grains and the new mineral assemblage reveals the metamorphic origin.

Overview

Characteristic metamorphic minerals are mica, garnet, aluminosilicates, chlorite, and serpentine. To give the proper name of a metamorphic rock, the petrologist refers to the nature of protolith, i.e., the rock prior to ► [metamorphism](#). Most metamorphism is isochemical, except for the gain or loss of water and other volatile components, that is, the metamorphic rock usually retains the chemical

composition of its precursor. When shale, a sediment rich in Aluminum, is metamorphosed, clay minerals are converted to aluminous minerals such as micas to produce a schist or metapelite. As metamorphic conditions increase, a part of the micas converts to feldspar and other minerals. When limestone is metamorphosed, it is transformed to marble. Schist, some types of gneiss, and marble are examples of metasedimentary rocks. Metamorphism of basalt produces amphibolite; metamorphism of granite produces orthogneiss.

The structure (shape, size, and spatial arrangement of minerals in the rock) is an essential characteristic of metamorphic rocks. Minerals may be distributed randomly, but commonly show a preferred orientation. When platy minerals such as micas are well aligned, the rock will show a planar structure or schistosity. At high metamorphic grades and with increasing strain, minerals segregate into bands to produce a gneissic texture. Elongated minerals such as sillimanite needles or strained minerals can then underline a linear feature named mineral lineation. The size and shape of grains can be used to identify the strain intensity and preferential direction of strain (finite strain ellipsoid). In some cases, the mineral association of a metamorphic rock is restricted to a specific pressure-temperature (P-T) domain or metamorphic facies. A small number of metamorphic facies, about 10, have been related to the wide range of P-T conditions that occur in the crust and uppermost mantle. Consequently, a metamorphic rock is named using the type of protolith and the metamorphic facies recorded by a specific set of minerals, for example, “blueschist-facies metapelite.” The metamorphic facies may be related to a specific geodynamic context: ► [subduction](#) results in high P-low T metamorphism (blueschist-facies). Another example, contact metamorphism, results when a shallow magmatic intrusion produces low P-high T metamorphism (hornfels metamorphic facies).

France

Keywords

Geotherm · Metamorphic reactions · Pressure · Temperature

Definition

Metamorphism is the process that modifies the texture, chemistry and/or mineralogy of a rock subjected to a change of physical conditions, usually an increase in temperature and pressure. Metamorphism is by definition a dominantly solid-state process, operating at all scales, from regional to micrometric, and within all types of rocks.

Overview

The field of metamorphism begins somewhat arbitrarily when diagenesis (the lithification and alteration of sediment) ends. This differs widely for different rock types (such as salt vs. a quartzose sandstone). A good criterion is whether

primary volcanic or depositional textures are still recognizable. For many rock types, metamorphism begins at a temperature around 150 °C. It ends when the rock becomes largely molten. The transition from metamorphism to magmatism is not straightforward; a rock is said to be metamorphic even when it contains a molten fraction if this fraction is localized and in a sufficiently small amount that the rock as a whole behaves as a solid. When material transfer is important (driven by melt, volatiles, or diffusion at high temperature), the system is chemically open and the bulk rock composition may be modified. This process is called ► [metasomatism](#). ► [Hydrothermal alteration](#) is considered a part of metamorphism (e.g., hydrothermalism of ► [Oceanic Crust](#)). In contrast, low-temperature weathering at the Earth's surface is considered a sedimentary process.

The changes induced by metamorphism are visible in the textures and types of rock-forming minerals. Prolonged heating induces crystal growth with the consequence that grain size increases systematically with increasing metamorphic grade. Deviatoric stress produces strain. As strain increases, the mineral grains become more elongated and commonly acquire a preferred orientation.

As pressure increases with depth, minerals like quartz (density = 2.66 g/cm³) may be transformed into high-pressure polymorphs such as coesite (density = 3.0 g/cm³). This metamorphic reaction results in a volume decrease. The time needed for such a change is relatively long and controlled by fluid, strain, or temperature. At room temperature and atmospheric pressure, the reaction coesite-to-quartz operates as well but is extremely slow. Because the stable mineral under these low P-T conditions is quartz, any coesite formed is metastable. Thus, metastable mineral assemblages that are preserved in metamorphic rocks on Earth surface can record earlier temperatures and pressures. They can help to define old geotherms (paleogeotherms), the record of how temperature varies with depth in the Earth's crust and mantle. On Earth, the rate and manner of temperature changes largely depends on the tectonic setting. The geotherm varies with the type of crust (continental or oceanic) and with the geodynamic

activity (stable craton, subduction, collision, or extension). Thus, metamorphic rocks are sources of information about specific geodynamic contexts. In some cases, metamorphic rocks record a series of metamorphic conditions through time, defining what is called a P-T-t (pressure-temperature-time) path.

Metasediment

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble, France

Definition

A metasediment is a rock of sedimentary origin that has been subjected to metamorphism. When the protolith (the sedimentary rock before metamorphism) is shale, metamorphism produces first schist and then paragneiss as temperature and pressure increase. As grain size increases, the rock acquires first a foliation (alignment of mineral grains), then a banding (alternating, thin layers of different mineral compositions), and the mineral assemblage changes to include minerals such as mica, garnet, and aluminosilicates. Metamorphism of pure limestone produces marble; that of chert quartzite, and that of banded-iron formation a magnetite-garnet rock. Metamorphism of impure silica or clay-rich limestone produces calc-silicate rocks. Sandstone is transformed into quartzite. Most Archean terranes contain metasediments which have been affected by at least low-grade metamorphism

(prehnite-pumpellyite facies: 250–350 °C and 2–7 kbars) which has either completely or partially reset most of the isotope systems.

Metasomatism

Bruce Yardley
School of Earth and Environment, University of
Leeds, Leeds, UK

Keywords

Chemical change · Metamorphism · Aqueous processes

Synonyms

[Metasomatosis](#)

Definition

Metasomatism is a group of processes by which a rock can change chemical composition while it recrystallises, remaining a coherent solid throughout. It is closely related to ▶ [metamorphism](#), which, however, is isochemical, apart from the loss of volatiles. Metasomatism can be subdivided into diffusion metasomatism, observed at the interface between contrasting rock types, and infiltration metasomatism, in which material is introduced in a fluid phase infiltrated from a remote source. Infiltration metasomatism is normally meant in general use of the term.

History

The term Metasomatism has been used in its general modern sense for terrestrial rocks since the nineteenth century, although some historical examples of metasomatic rocks are now interpreted differently. Metasomatism has been recognized in meteorites, primarily chondrites, since the end of the twentieth century, and is now recognized as an important process, at least locally, in the early Solar System.

Overview

The most widespread metasomatism on Earth occurs in permeable rocks, often at relatively shallow depths in the crust. This includes the modification of sandstones by formation waters, notably albitization of plagioclase feldspar, albitization of fractured crystalline basement rocks as they return to the surface, and the alteration of basalts to spilites (metabasalts which have anomalously high Mg-contents) at mid-ocean ridges. At greater crustal depths, metasomatism of limestones or marbles intruded by granite results in the formation of skarns, while metasomatism has been invoked to account for the composition of some mantle rocks, especially potassic xenoliths (xenolith = a deep-seated rock fragment transported to surface during magma emplacement and eruption), where it may be ascribed to melt migration.

A theoretical understanding of metasomatism was developed by D.S. Korzhinskii in the 1930s. The Korzhinskii Phase Rule relates the number of phases and independent degrees of freedom in a system to the number of immobile chemical components, rather than the total number of components. As a result, a rock which has experienced substantive chemical change by migrating fluids has a relatively small number of phases while solid solution minerals in metasomatic rocks have rather uniform compositions, despite the potential for variation. Despite the essential role of water in metasomatism, many metasomatic minerals do not contain water in their structure.

The presence of hydrous minerals in chondritic meteorites has been known for many years, but metasomatism, implying chemical transport

through the medium of water, has only been recognized over the past quarter century. CV chondrites show a range of metasomatic minerals, mainly rich in Fe and/or Ca, alkalis or halogens, and these are consistent with subsolidus growth in an aqueous environment. CO chondrites show a more restricted range of secondary minerals. In both cases, metasomatism is believed to have occurred predominantly in an asteroidal environment, although some meteorites show evidence for later metasomatic effects also. The case for metasomatism of some Martian meteorites is based on the presence of REE-enriched minerals which are out of equilibrium with the major silicate phases, suggesting that they grew subsequently as REE were introduced.

Molecular Evolution Department, Centro de Astrobiología (INTA-CSIC), Torrejón de Ardoz, Madrid, Spain

Keywords

Transcription · Gene expression · Microbial diversity · Environmental microbiology · Complex microbial communities

Synonyms

[Environmental transcriptome](#); [Microbial community gene expression profile](#); [Microbial community RNAs](#); [Whole community transcripts](#)

Definition

Metatranscriptome refers to the total content of gene transcripts (RNA copies of the genes) in a community, considered as a unique entity, at a specific moment of sampling. Metatranscriptome varies with time and environmental changes. The techniques applied to obtain the whole expression profile in a community and to follow the dynamics of gene expression patterns over time or environmental parameters are known as metatranscriptomics. It improves our understanding of the structure, function, and adaptive mechanisms in complex communities and, together with other “omics,” is applied to fields such as medicine, biotechnology, and, particularly, in microbial ecology.

History

The study of the total expressed genes in a cell or organism at a certain moment started in the 1980s using techniques such as northern blot and reverse transcription coupled to polymerase chain

Metasomatosis

- [Metasomatism](#)

reaction amplification (RT-PCR). The development of microarrays technology in the 1990s (Schena et al. 1995) enabled the characterization of gene expression for hundreds or thousands of genes at once, thus opening the door to the study of single transcriptomes (Zhou et al. 2003) and complex environmental transcriptomes (Parro et al. 2007). It was Leininger et al. (2006) who reported the first metatranscriptome from an ammonia-oxidizing prokaryote community in soils, thanks to the development of massive sequencing platforms. Since then, metatranscriptomic analysis has revolutionized the field of gene expression profiling, extending its scope of application to the analyses to small non-coding RNAs (Shi et al. 2009; Herbig and Nieselt 2011).

Overview

Metatranscriptomics provides insights into the metabolic activities, functions, and regulation in environmental microbial communities. This powerful tool is crucial to investigate the metabolic traits of environmental communities as a whole, where unculturable microorganisms constitute the vast majority of the population (Bailly et al. 2007; Embree et al. 2013). The first attempts to characterize complex communities by sequencing their mRNAs led to the discovery that Archaea were the most predominant ammonia oxidizers in soils (Leininger et al. 2006). Since then, this technique has been applied to typify many ecosystems including soils, marine, and freshwater as well as the human microflora, making it possible to determine the composition of complex microbial communities, the function of individual microorganisms in the environment, and the role of microbial interactions in global biogeochemical cycles (Embree et al. 2013). In addition, *scientists* are using metatranscriptomics to explore the human microbiome, in order to shed light on its role in the human physiology (Gosalbes et al. 2011). Some studies have shown the microbiome interaction with the immune and nervous systems to be also related to obesity, cardiovascular risk, and diseases such as the inflammatory bowel disease (Clemente et al. 2012).

The understanding of the role played by the human microbiota in its host, through metatranscriptomic approaches, could contribute to develop new therapeutic strategies in the near future.

Metavirome

Josefa Anton

Department of Physiology, Genetics and Microbiology, University of Alicante, Alicante, Spain

Keywords

Virus · Metagenome · Environmental sample

Synonyms

[Viral metagenome](#)

Definition

The metavirome is the ► [metagenome](#) (sum of genomes) of the viruses present in a sample, obtained by the extraction and sequencing of the viral genetic material present in the analyzed sample. It can also be defined as the metagenome of a viral assemblage.

History

This term was coined by J. H. Paul and M. B. Sullivan in 2005 to refer to the studies on the uncultivated marine ► [virus](#) community ► [genome](#) (Paul and Sullivan 2005).

Overview

The first study on an environmental metavirome was published in 2002 (Breitbart et al. 2002), which analyzed the metagenome of uncultured marine virus communities. Since then, studies on the metaviromes from different environments, such as human feces, rice paddy soil, solar salterns, marine water and sediments, coral, freshwater, microbialites, hot springs, Antarctic lakes, fish, mosquitoes, reclaimed water, and grapevine, among others, have been carried out by several authors. Most of the studies have been focused on dsDNA metaviromes, although ssDNA and RNA

viruses have also been analyzed using this approach. The analysis of metaviromes allows for the direct study of natural virus communities and circumvents the problems derived of the fact that the majority of viruses cannot be cultured because their hosts cannot be readily isolated.

There are several protocols for constructing metaviromes that normally follow this scheme: first, cells are removed, and the viral assemblage is concentrated by tangential filtration and/or ultracentrifugation; then viral nucleic acids are extracted by means of different protocols (Thurber et al. 2009; Santos et al. 2010) and sequenced. In some cases, nucleic acids are cloned into plasmids and/or fosmids (cloning vectors that allow for the cloning of large DNA fragments) prior to sequencing, or amplified using different protocols (Paul and Sullivan 2005; Thurber et al. 2009) and directly sequenced using high-throughput sequencing methods. Pros and cons of every approach are discussed in Thurber et al. (2009). Once the metaviromic sequences are available, they can be analyzed and compared with databases using several bioinformatic tools.

Metavirome characterization allows the cataloging of the viruses present in a given environment as well as the descriptions of relative abundance of different virus types. Thus, the analysis of metaviromes, in addition of ascertaining the viral diversity in a sample, makes it possible to reconstruct the structure of uncultured viral communities (Edwards and Rohwer 2005), and also to identify viral encoded functions. However, it has the main drawback of the high number of unknown genes found when trying to identify the protein-coding regions or open reading frames (ORFs) present in the metaviromes. For this reason, methods for metavirome analysis (Angly et al. 2005; Willner et al. 2009) have been developed that do not depend on gene annotation and allow for the comparison of different viral metagenomes corresponding to different environments, as well as for functional metagenomic approaches (McDaniel et al. 2009).

Keywords

CAIs · Chondrite · Meteorite · Protoplanetary disk

Definition

Allende is a meteorite that fell in Mexico in 1969. Roughly 2 t of that CV3 ► [carbonaceous chondrite](#) were found. Allende is one of the most studied meteorites, because it contains abundant and large ► [CAIs](#), which are believed to be the first solids to have formed in the solar system.

Overview

The Allende meteorite fell early in the morning of Saturday, February 8, 1969, 7 months before the fall of ► [Murchison](#) (CM2 chondrite rich in amino acid) and 4 months before the return of 22 kg of Moon rocks by the Apollo 11 crew. After a bright fireball that was seen in Texas and New Mexico, thousands of stones fell near the small village (pueblito) of Allende, south of Chihuahua, in northern Mexico.

A large stone (15 kg) fell near a house and some pieces were brought to the office of the newspaper *El correo de Parral* the same day. News of the meteorite fall was published the same evening. Mexican and US scientists collected rocks the next weeks. Eight months after the fall, a 110-kg sample was found. In total, 2 t of rocks were recovered (see Fig. 1).

Allende belongs to the class of CV3 chondrites, an important group of carbonaceous chondrites, which represent roughly 0.6% of the meteorite falls.

The fall of Allende was a landmark in ► [cosmochemistry](#), because it led to the rediscovery of calcium-, aluminum-rich inclusions (CAIs). These white inclusions were first reported and described in 1968 by Mireille Christophe Michel-Lévy in a French journal, which did not receive the attention it deserved (Christophe Michel-Lévy 1968). The abundance of CAIs in Allende is

Meteorite, Allende, Fig. 1 A piece of the Allende meteorite kept at the Muséum National d'Histoire Naturelle in Paris (sample 2870, 144 g). The nearest face is still covered by the fusion crust (see entry “► [Cosmochemistry](#)”). The white inclusion is a calcium-, aluminum-rich inclusion (see entry “► [CAIs](#)”). (Picture C. Fiéni [MNH])

roughly 10%, while the mean abundance in CV3 chondrites is 4.8%, explaining why CAIs had been overlooked until Allende fell, though ten other meteorites of that kind were known in 1969.

CAIs' mineralogy indicates that they were the first solids to form in the protoplanetary disk. This is confirmed by their old Pb-Pb age and their high abundance of short-lived radionuclides. CAIs can potentially reveal the physicochemical conditions in the protoplanetary disk, 4567 Gyr ago (see ► [“CAIs”](#)).

The high abundance as well as the large size (millimeter objects are common, centimeter objects are not rare) of Allende CAIs explain why the study of these key objects has been dominated by samples coming from the Allende chondrite for at least 30 years. In addition, it was widely believed that CAIs within Allende did not suffer any secondary event in its parent-body and that the record of the protoplanetary disk was kept intact within these samples. Numerous chemical, mineralogic, and isotopic studies were made over the last 30 years on these objects.

In the mid-1990s, Sasha Krot and collaborators demonstrated, however, that Allende endured metamorphism and metasomatism in its parent-asteroid. This means that Allende CAIs are not as pristine as it was thought. Furthermore, it appears that many of the CAIs studied within Allende (type B CAIs) are absent from other chondrites and that most of our knowledge on CAIs is based on unrepresentative samples.

Definition

The Murchison meteorite is a carbonaceous chondrite belonging to the CM group (Mighei like). It was formed 4.56 billion years ago and has remained undifferentiated since then, although it is classified as a CM2 chondrite, meaning it shows signs of aqueous alteration. This meteorite contains about 30% of chondrules, in volume, and 70% of a fine-grained matrix. This matrix hosts a diverse suite of organic compounds, some of them being considered as potential prebiotic molecules.

History

On 28 September 1969, at about 10:58 a.m., near the town of Murchison, Victoria, in Australia, a bright fireball was observed that broke into three distinct fragments. About 30 s later, a tremor was

heard. Many specimens of this Murchison meteorite were found over an area larger than 13 km², and the total-collected mass exceeds 100 kg. This meteorite has since been the reference material to investigate extraterrestrial organic matter.

Overview

The Murchison meteorite belongs to the CM group of carbonaceous chondrites. These chondrites are rich in volatiles, including carbon, and are among the most chemically primitive meteorites. Murchison contains presolar grains including silicon carbides that are 7 billion years old (Heck et al. 2020). Like most other CM chondrites, Murchison contains centimeter-size inclusions of refractory oxides and silicates (calcium-aluminum-rich inclusions; the CAIs). These inclusions were condensed from a gas of solar composition at high temperature and are interpreted as the first stages of the cooling of the protosolar disk that eventually led to the planets of the solar system. Murchison exhibits features related to extensive alteration by water-rich fluids on its parent body, few million years after its formation 4.56 billion years ago.

Basic Methodology

Since its discovery, the Murchison meteorite has been studied using a large range of analytical techniques, from electron microscopy to investigate its petrographic and mineralogic properties, to isotope ratio mass spectrometry to determine the age and the origin of its components. Studies have been performed in situ on intact pieces, on polished preparation of sections and by applying chemical treatments (including acid leaching) to separate its organic and inorganic constituents. As it happens to be rich in well-preserved organic matter, Murchison has been and remains the prime target for organic analysis of extraterrestrial compounds. At every major improvement in analytical chemistry, new discoveries are made about the organic composition of the Murchison meteorite.

Key Research Findings

The Murchison meteorite, as other CM chondrites, contains organic molecules formed at low temperatures (i.e., between 30 and 300 K). Several lines of evidence indicate that the interior portions of Murchison are well-preserved and are indigenous to the meteorite, that is, not modified or contaminated on Earth. A 2010 study using very high mass-resolution mass spectrometer has reported more than 14,000 different molecular compositions in a methanol extract of the Murchison meteorite (Schmitt-Kopplin et al. 2010). This represents a huge molecular diversity of organic molecules formed by abiotic processes. The Murchison meteorite contains various organic molecules that are involved in life forms on Earth: amino acids, as well as nucleobases or sugar-related molecules (Callahan et al. 2011; Cooper and Rios 2016; Koga and Naraoaka 2017). They represent a potential molecular source for the chemistry that led to the origin of life. The main organic component is recovered as an insoluble organic macromolecule, constituted by small aromatic units connected by short and branched aliphatic chains. The aromatic units host N- and S-moieties (pyrroles and thiophenes group), whereas O groups (ester or ether functions) can be found in aliphatic chains (Alexander et al. 2017).

Judging from the numerous interpretations on the origin of these organic compounds that can be found in the literature, it can be considered that the organic matter of Murchison reflects a mixture of different origins (Remusat et al. 2016). While some precursor compounds of the insoluble organic matter may have been formed in the protoplanetary disk or the parent molecular cloud by photochemical reactions (such as the polycyclic aromatic hydrocarbons), others – the small and soluble molecules – were likely processed inside the parent body of the meteorite itself. The pre-accretionary origin is supported by significant enrichments in heavy isotopes of H and N, likely related to synthesis occurring at low temperature under irradiation. Ion-molecule reactions are often involved to account for large D/H ratios in the insoluble organic matter, for instance, which exhibits numerous D-rich hotspots and organic

radicals. Nevertheless, the extent of the alteration of the D/H signature of organic molecules by the aqueous alteration on the parent body remains discussed, making it dubious to determine the exact origin of organic precursors.

The emblematic example of low-temperature molecules is the amino acids that are often considered as prebiotic components of life, as well as nucleobases or sugar-related molecules. More than 92 amino acids have been identified in Murchison including 12 actually involved in the living-protein world. For example, glycine, α -alanine, and glutamic acid, as well as unusual ones like isovaline and β -alanine are present in Murchison. It is usually assumed that a large part of amino acids was formed on the parent body of carbonaceous chondrites during aqueous alteration, most probably by the Strecker cyanohydrin synthetic mechanism. Michael addition, reductive amination, and CO₂ addition are additional mechanisms proposed to account for non α -amino acids. Laboratory data on the deuterium retention of amino acids during Strecker synthesis indicates that, with the exception of glycine, meteoritic amino acids can be formed by this mechanism from highly deuterated precursors. The origin of these deuterium-rich precursors (solar or interstellar) is still in debate. In addition, the isotopic fractionation of carbon and nitrogen occurring during Strecker synthesis does not account for the large enrichment in ¹³C and ¹⁵N observed among several families of organic molecules; the possible – and proposed – interpretations of such a huge fractionation have not been experimentally substantiated.

In the 1970s, several studies reported that amino acids were racemic (i.e., the chirality of their enantiomers are equally left and right handed), indicating that they are not terrestrial contamination. However, refinements of analytical chromatographic techniques have shown that enantiomeric excesses do exist in some amino acids. This finding has reopened Pandora's box of possible terrestrial contaminants. The debate was finally closed owing to an outstanding high-tech analytical technique where the nitrogen isotopic compositions of each enantiomer were measured individually. These isotopic compositions are out of the terrestrial range, and the two

enantiomers are equally enriched in ^{15}N relative to their terrestrial counterparts (Engel and Macko 1997). Since the terrestrial contamination would have left its isotopic signature on the L-enantiomer, indubitably an extraterrestrial source favored L-enantiomers in the early Solar System. Furthermore, L-excess has also been reported for non-protein amino acids, for example, isovaline (Glavin et al. 2020). Interestingly, some sugar derivative molecules detected in Murchison exhibits excess in the right-handed form (Cooper and Rios 2016). It is possible that the origin of the homochirality of life (i.e., the occurrence of only the left-handed amino acids and right-handed sugars) was triggered on Earth by the deposition of chiral molecules contained in meteorites. The origin of these enantiomeric excesses has been related to irradiation by circular polarized UV-light of ices where organic precursors were formed and that would be accreted on parent bodies (de Marcellus et al. 2011), or to the occurrence of chemical reactions at the surface of minerals having capabilities to sort enantiomers during aqueous alteration (Glavin et al. 2020).

Meteorites resembling Murchison may have delivered molecules that have influenced the origin of life on Earth (d'Ischia et al. 2021). Although it is difficult to estimate the flux of extraterrestrial carbon to the early Earth from the present-day observations, it has been calculated that around 10^9 kg of organic carbon could have been delivered to the planet per year in the first billion years of its existence, mostly incorporated in dusty particles like interplanetary dust particles (IDPs) or micrometeorites (Rojas et al. 2021). This flux is two to three orders of magnitude higher than nowadays. While organic compounds delivered by small particles may suffer from atmospheric entry, delivery by larger bodies like the Murchison meteorite brings intact prebiotic molecules on the surface of Earth.

Future Directions

The discussion about the input of extraterrestrial organic molecules on Earth has several ramifications. Even if it can be demonstrated that amino

acids or nucleobases can “safely” land on the primitive Earth, would that prove the origin of the world of left-handed amino acids in which we live? What is the amount – or the concentration in a sterile ocean – of prebiotic molecules necessary for a life ancestor to be assembled? Are high concentrations and a large molecular diversity of organic molecules required for life to emerge? The answers to these questions are largely unknown; they are related to a credible model of the chemical pathways that gave rise to life.

- sample of the CI ► [Carbonaceous Chondrite](#) group, which represents the most primitive bodies of the solar system. Its composition is identical to that of the solar photosphere, except for the lightest elements (roughly from hydrogen to nitrogen). An important discovery was the detection of a high abundance of isotopically anomalous xenon, which could be the signature of presolar material. The absence of high-temperature components within the Orgueil meteorite is explained by an important aqueous alteration of its parent body. The Orgueil meteorite also contains amino acids (a few ppm), although this abundance is below what can be observed in CM meteorites such as Murchison. Interestingly, a significant L-enantiomeric excess of isovaline (a non-biological amino acid) is measured in the meteorite Orgueil (enantiomeric excess of about 15%). Some studies have suggested that Orgueil could have a cometary origin, although this hypothesis remains quite uncertain.

Definition

A meteorite is a macroscopic rock originating from interplanetary space and which has naturally landed on a planetary surface (e.g., Earth).

History

A few metallic artifacts predating the Iron Age, such as Tutankhamun's dagger, show an iron-nickel composition characteristic of iron meteorites. Meteorite falls have been reported since the earliest Antiquity and some of them have been worshipped as baetyls, such as the Elagabal stone in Emesa, whose eponymous priest achieved temporary fame as a Roman Emperor in 218–222 A.D. These meteorites are however lost, and the oldest falls with preserved samples date back to 861 (Nogata, Japan) and 1492 (Ensisheim, then a part of the Holy Roman Empire and now France).

While some Greek philosophers entertained a cosmic origin of those objects, others, starting with Aristotle, envisioned a formation within the atmosphere. With the advent of the Enlightenment, the very reality of meteorite falls was questioned, as many objects held by folklore to be of celestial origin turned out to be fossils or prehistoric artifacts. Nonetheless, the scientific community accepted the existence of meteorites (as extraterrestrial objects) at the end of the eighteenth century, in a process which roughly started with the 1794 publication of Ernst Florens Friedrich Chladni's book on the cosmic origin of bolides and concluded with the 1803 meteorite shower near L'Aigle in Normandy, which was extensively studied by Jean-Baptiste Biot (Jacquet 2017).

Chemical analyses had just started to be routinely applied to meteorites (which had rapidly revealed iron-nickel alloys as a diagnostic of most meteoritic material; Jacquet 2017). Over the next century, the various classes of meteorites would gradually be recognized, in tandem with the development of geology and mineralogy (Jacquet 2017). The discovery of asteroids

starting with Ceres in 1801 paved the way for the recognition of the parent bodies of most meteorites, though it would take the installation of dedicated camera networks to confirm, from orbital reconstruction, that these originated from the asteroid main belt between Mars and Jupiter (starting with the Pribram fall in 1959; Jacquet 2017). The advent of the Space Age (inaugurated by Sputnik 1 in 1957) and microanalytical techniques meant a boost in the understanding of meteorites as remnants of the early Solar System. Meteorite finds also began to pour from hot and cold deserts. Starting at the turn of the millennium, space probes were sent to study asteroids and comets, and even returned first-hand samples thereof, which allowed direct linking of meteorites with spectroscopic taxa of these minor solar system bodies (Jacquet 2017).

Overview

Fall Phenomena

A meteorite (or, strictly speaking, a *meteoroid* so long it has not reached the ground) enters the Earth atmosphere at a (“cosmic”) velocity between 11 and 72 km/s (corresponding to Earth's escape velocity and the relative speed of a meteoroid on an hyperbolic orbit meeting Earth head-on, respectively). Such a supersonic velocity entails the formation of a bow shock, where air compressed and heated in the vicinity of the rock glows and gives rise to a visible light phenomenon called a *meteor* (or “bolide”). The hot air also melts and partly vaporizes the surface of the meteorite, which thereby loses mass in a process called *ablation*, and may entirely destroy meteoroids smaller than about 10 cm in diameter (unless in the micrometeorite size range). The drag due to the ram pressure (i.e., the pressure of the compressed gas in front) usually removes all the cosmic velocity at ~20 km altitude (the *retardation point*), and the meteor goes extinct and the meteorite falls at terminal velocity (*dark flight*). Most of the time, before the retardation point, the ram pressure overcomes the tensile strength of the meteorite and causes its explosion – adding to the sonic booms accompanying the

meteoroid – forming a *meteorite shower*. The individual meteorites then distribute themselves on the ground over an elliptical area called a *strewn field*, with the heaviest usually travelling furthest due to their inertia. Freshly fallen meteorites are covered by a thin (~mm thickness), usually black *fusion crust* which is the quenched remnant of the melted surface during ablation.

Meteoroids larger than about 10 m in size are not efficiently slowed by atmospheric drag and thus impact the ground at close to their initial (cosmic) velocity. Such hypervelocity impacts generate explosion craters, which may attain 20 times the impactor diameter. Depending on the energy of the impact and distance from the epicenter, the substratum (and the impactor) may be fractured, melted, or vaporized, generating a suite of impact-created rocks called *impactites*. These include shatter cones, lithic breccias, suevites (breccias with melt inclusions), and impact melt rocks, and sometimes even impact glasses. Some melted ejecta may travel far from the impact before landing as glasses called *tektites*; such as the moldavites mostly found in the Czech Republic and formed by the impact at Nördlinger Ries in Bavaria (Germany), or the australasites which scattered over Southeast Asia and Oceania, but whose source crater, presumably in Indochina, has not yet been identified (Jacquet 2017). Only ~200 impact craters are known worldwide because geological activity on Earth has erased most others. The oldest impacts may be then only manifest by impact spherule deposits (microtektites (crystal-free), microkrystites (crystal-bearing)) in the sedimentary record. Most meteorite craters formed in prehistoric times and lack any surviving meteorite (either because of weathering or vaporization upon impact), so their recognition depends essentially on the aforementioned impactites. The largest (but heavily eroded) impact craters are Vredefort (South Africa, 300 km diameter) and Sudbury (Canada, 250 km), both about 2 Ga in age. Next comes the Chicxulub crater in the Yucatan peninsula (Mexico, 200 km) which has notoriously attracted attention since its formation coincides with, and may be the cause of, the extinction of non-avian dinosaurs 66 Ma ago (Jacquet 2017).

Meteorites are named after the place they were found, under the auspices of the Nomenclature Committee of the Meteoritical Society (Jacquet 2017). A meteorite whose fall has been witnessed is called a *fall* (or an “observed fall”); other meteorites are simply *finds*. Falls are often favored by meteoriticists because of their minimal weathering, but nowadays, they are greatly outnumbered by finds (by a factor of ~50) which may be the only form in which some rare types are known. Finds are especially numerous in deserts, where dryness and/or cold may allow preservation for tens of millennia, and, if the soil is light-colored, dark (fusion-crust) rocks may be more conspicuous (although desert varnish may partly mimic fusion crusts). Numbers need to be added to the names of the associated dense collection areas to distinguish different meteorites found there, for example, “Dar al Gani 400” refers to the 400th find of the Dar al Gani area (in Libya). Some differently numbered meteorites may be actually *paired*, that is, associated with the same meteorite shower. In Antarctica, where the wind-driven erosion of glaciers at the base of mountains chains has generated considerable accumulations of exposed meteorites, the numbering rewinds at each new field season, with the year being indicated by the first two digits. For example, Allan Hill 84001 (or ALH 84001) is the first find of the 1984–1985 search campaign at Allan Hill. While meteorite collection in Antarctica is exclusively performed by scientists, hot desert finds are mostly made by private meteorite hunters, which may result in the lack of available find coordinates (critical for pairing assessments). Such data are missing for the many “Northwest Africa” (shorthand: “NWA”) meteorites (Jacquet 2017).

Meteorite Parent Bodies

The *parent body* of a meteorite is its celestial body of origin. If the immediate parent body of a meteorite is itself a fragment of some prior object, it is worthwhile to distinguish between *primary* (i.e., as originally formed at the beginning of the Solar System) and *secondary* parent bodies. Usually, discussions on the parent body of some meteorite group refer to the primary parent body (Greenwood et al. 2020).

The orbits of most falls captured on cameras have their aphelia in the main belt of asteroids, between Mars and Jupiter, which must be the source of the vast majority of meteorites (Jacquet 2017). A meteoroid, in essence, is simply a small asteroid, and there is no sharp size limit between “meteoroids” and “asteroids.” An *asteroid* should certainly be big enough to be telescopically observable, but meter-size objects can be observed if they approach Earth sufficiently closely. For instance, asteroid 2008 TC₃, 2–5 m across, was discovered hours before actually hitting Earth in 2008 – it ended as a meteorite shower over Sudan, whose remnants have subsequently been recovered and named Almahatta Sitta (Jacquet 2017).

A designation such as “2008 TC₃” above is in principle only provisional; once the orbit of a newly discovered asteroid is sufficiently well-determined, it may be assigned a number and a name (different from that of the discoverer, unlike for comets). The first discovered (and largest, with 950 km diameter) asteroid is 1 Ceres (or simply “Ceres”), the second 2 Pallas, etc. Over a million asteroids have been observed to date.

Most meteoroids are liberated from their parent asteroids through impacts. Many meteorites retain evidence of shock effects such as brecciation or shock veins. Many asteroids are merely rubble piles of material reaccumulated after catastrophic collisions. Some asteroids are binary (i.e., comprise two objects orbiting around each other), such as Didymos whose satellite Dimorphos will be impacted by the DART probe to test near-Earth asteroid deflection strategies. Others, while free of each other’s gravity, may still form a cluster in orbital element space which is called an asteroid “family.” The Gefion family (named after its main member, 1272 Gefion), for example, may have formed 470 Ma ago, as evidenced by an overabundance of fossil meteorites in the corresponding (Ordovician) sedimentary strata on Earth (Jacquet 2017).

Impact ejection by itself will not send a meteoroid into an Earth-crossing orbit (Jacquet 2017). However, a meter-size meteoroid is prone to orbit alteration via the Yarkovsky effect. The Yarkosky effect is the recoil in the orthoradial direction that a rotating object may undergo from delayed

reemission of sunlight. So significant specific angular momentum may be gained or lost because of its large surface/volume ratio, and the meteoroid may drift and eventually reach resonances where gravitational interactions with Jupiter will rapidly increase the eccentricity of the orbit, which may cross those of inner planets.

During its interplanetary transit, a meteoroid is exposed to galactic cosmic rays (energetic charged particles) which entail spallation reactions and the synthesis of new (*cosmogenic*) nuclides. This ceases after impact on Earth which is shielded by its atmosphere. The measurement of such nuclides (especially for noble gases, e.g., neon-21, which are depleted in the starting rock; Turekian and Holland 2014) can allow the duration of the interplanetary transit (the *cosmic ray exposure age*) to be calculated (Turekian and Holland 2014). Measurement of those cosmogenic isotopes which are also radioactive – and whose decay is not compensated by production after reaching our atmosphere – also allow estimation of the *terrestrial age* of a find (which is usually much shorter than the exposure age). For stony meteorites, the cosmic ray exposure age does not exceed 104 Ma, and is generally much less, but for irons, older ages up to 2.2 Ga (for the Deep Springs meteorite) are known. Clusters of exposure ages for a given meteorite group (e.g., around 7 Ma for H ordinary chondrites) provide evidence for a common ejection event of the associated meteorites, and thus a common parent body of origin.

While, historically, asteroids have been envisioned as debris of a former planet missing between Mars and Jupiter, the main belt currently only comprises a total mass of 3×10^{21} kg (with a third locked up in Ceres), not even a 20th part of the Moon. The diversity and primitivity of most asteroids are also inconsistent with derivation from a former planet. Rather, the region between Mars and Jupiter may not have harbored enough mass to ever build a planet, which may also explain the mass of Mars, whose mass is an order of magnitude below that of Earth and Venus. It is possible that inward-then-outward migration of Jupiter largely emptied that area (see the “Grand Tack” scenario in ► “Planet

Formation”), but other scenarios are conceivable. Whatever that may be, the asteroid main belt is essentially a repository of planetesimals left over from planetary accretion 4.5 Ga ago (Jacquet 2017).

Asteroid classification is based on reflectance spectra. To a first approximation, the main asteroid belt consists of an inner region (<2.6 AU, where the Astronomical Unit (AU) refers to the Earth-Sun distance, about 1.5×10^{11} m) dominated by dry silicate asteroids grouped in the S taxonomic class, and an outer region dominated by the “C complex,” whose members have a low albedo suggestive of a carbonaceous composition. The link between S type asteroids and ordinary chondrites has been confirmed by the sample-return mission Hayabusa 1 on asteroid Itokawa (Nakamura et al. 2011). The comparison between C-complex asteroids and carbonaceous chondrites will be informed by the study of samples returned by Hayabusa 2 (see ► “Hayabusa Missions”) and Osiris-Rex from asteroids Ryugu and Bennu, respectively (Jacquet 2017).

Some meteorites may actually derive from comets (as entertained for Orgueil based on reconstruction of its orbit; Gounelle et al. 2006). Dust returned from comet Wild 2 by the Stardust mission in 2006, as well as micrometeorites, suggests kinship to carbonaceous chondrites, so the difference may not be readily recognizable, and there must essentially be a continuum between (C complex) asteroids and comets in the outer solar system (Gounelle et al. 2006). The Grand Tack scenario even considers C complex asteroids as imported from the outer disk. Some main belt asteroids may be in fact dormant comets, as sometimes suggested by episodic activity, which may be due to recent impacts exposing the icy subsurface.

A small minority of meteorites have planetary origins. Lunar meteorites have been recognized based on comparison with samples returned by the Apollo and Luna missions. Other meteorites, long referred to as SNC meteorites (after Shergotty, Nakhla, and Chassigny which were the prototypes of the main varieties), are considered to be of Martian origin, chiefly because of their young crystallization age (mostly a few hundreds of Ma, although some, such as the “Black Beauty”

NWA 7034, may date back up to 4.4 Ga), which is inconsistent with an asteroidal origin, and the correspondence between gases trapped in impact glasses and Martian atmosphere analyses by the Viking landers (e.g., Turekian and Holland 2014).

Basic Methodology

The Petrological Classification of Meteorites

The classification of meteorites developed in the nineteenth century and, after some simplifications by Prior (1920), achieved more or less its contemporaneous form in the 1960s–1970s (e.g., Van Schmus and Wood 1967). Nowadays, meteoritists distinguish two overarching petrological categories: *primitive* meteorites (or *chondrites*) which have undergone little change since their parent bodies accreted, and *differentiated* meteorites, which have undergone melting and igneous fractionation. The difference in the fate of the planetesimals in this respect was dictated by the size of the planetesimal (i.e., its surface/volume ratio controlling cooling) and the abundance of short-lived radionuclides present at the time of accretion. The chief heat source was aluminum-26 (half-life: 0.7 Ma), whose past existence is evidenced by excesses in its daughter isotope magnesium-26 correlated with the Al/Mg ratio in meteoritic material; iron-60 (half-life: 2.6 Ma), once considered an important contributor, is now deemed to have been too low in abundance. Impacts may have also locally contributed to heating on planetesimals. Since ^{26}Al was most abundant in the earliest first million years of the protoplanetary disk (with original $^{26}\text{Al}/^{27}\text{Al}$ ratio of $\sim 5 \times 10^{-5}$), the earliest formed planetesimals tended to differentiate more easily, as confirmed by Hf-W dating of iron meteorites. Paradoxical as it may seem, the parent bodies of differentiated meteorites thus accreted earlier than those of chondrites (accreted ~ 2 – 3 Ma after the formation of the Solar System), even though only the latter retain the oldest solids of the Solar System.

Primitive Meteorites and Their Components

Chondrites make up 86% of falls. Their primitivity is evinced by the close correspondence of the

nonvolatile elements with the (spectroscopically measured) solar photosphere (with the exception of lithium, underrepresented in the Sun because of its destruction in an early stage of its nuclear history), especially for the carbonaceous chondrite Orgueil, which may serve as a reference material for solar abundances. Chondrites are basically conglomerates of the diverse mm-size solids that populated the solar protoplanetary disk during its few million years of lifetime (before dissipation), cemented by a fine-grained matrix, and such have been aptly termed “cosmic sediments” (McSween 1999).

Chief among them are the eponymous *chondrules* (from the Greek for “granule”) which are mm-size silicate spheroids which show evidence of formation as solidified droplets. Most of them exhibit porphyritic textures, with randomly oriented olivine and pyroxene crystals set in a glassy (or devitrified) mesostasis, a texture indicative of extensive but incomplete melting, with sometimes identifiable relicts of precursor material. Others have been entirely melted and undercooled before crystal nucleation, hence spectacular barred or radial textures. Chondrules may also contain metal and sulfide grains and may be the source of those found outside them as well. Some chondrules collided while hot and formed “compound chondrules.” The nature of chondrule-forming episodes, which may have lasted minutes, hours, or days, is arguably the deepest mystery of cosmochemistry. Two broad categories of scenarios are still contending for the favors of the community: “Planetary scenarios” form chondrules on an early generation of planetesimals, for example, in impact plumes (whether the melting is due to the energy of the impact itself, or in a preexisting magma ocean). “Nebular scenarios” have them formed in the general protoplanetary disk (also called “the solar nebula”), by melting of “nebular” (i.e., preaccretionary) precursors, for example, during the passage of shock waves (e.g., such as attend planetary embryos on eccentric or inclined orbits). Nebular scenarios were preferred from the 1980s through the 2000s, for example, because of the occurrence of nebular relict grains. However, planetary scenarios have regained momentum following evidence (e.g., from FeO or volatile

contents, or compound chondrule frequencies) that chondrule-forming regions were enriched in solids by orders of magnitude compared to the expected average background disk.

Refractory inclusions are a minor component of chondrites, but are the oldest dated solids of the Solar System, predating the chondrules by typically 1–3 Ma, with a Pb-Pb age of 4567 Ma commonly held to be “time zero” of the protoplanetary disk. Refractory inclusions comprise *calcium-aluminum-rich inclusions* (CAIs) and (somewhat less refractory) *amoeboid olivine aggregates* (AOAs). They are called “refractory” because their mineralogy corresponds to the first solids to appear in a cooling gas of solar composition (at ~1500–1800 K) according to thermodynamic calculations. A condensation origin in the disk seems likely, although some CAIs show (mass-dependent) heavy isotope enrichments suggestive of evaporation residues. Many refractory inclusions in general seem to have suffered several high-temperature episodes, sometimes leading to their melting (which may or may not be comparable to mainstream chondrule-forming events). The high temperatures required for CAI formation suggest an origin close to the Sun. While solar irradiation would only heat the very inner disk edge to the desired level, the dissipation of turbulence may produce the required heating, at least intermittently, further away, perhaps up to a heliocentric distance of an AU or so, especially in the early stages of the disk evolution.

In the most pristine chondrites, the *matrix* appears as an aggregate of micron-size crystalline and amorphous silicates and opaque phases. The matrix is composite in origin. There certainly are debris of the above high-temperature components and byproducts of their formation (in particular in fine-grained rims around chondrules). No less certainly, the matrix also contains dust that escaped any high-temperature processing in the disk. Indeed, monomineralic grains of very anomalous isotopic ratios (deviating from solar values sometimes by orders of magnitude) have been found: They are interpreted as intact condensates from the atmospheres of dying stars (red giants, supernovae, etc.) predating the formation of the Sun and are thus referred to as *presolar grains*.

They offer unique insight into stellar nucleosynthesis and our interstellar heritage. Most presolar grains, which originally made the bulk of the disk dust, have been destroyed, and those identifiable today never exceed a 1000th part of the matrix but other grains, for example, such grown in the interstellar medium itself, may not be isotopically recognizable and thus the exact extent of unmodified interstellar heritage in chondritic matter is not known. Matrix is the carrier of organic matter (in diffuse form or in micron-sized particles) and water (or rather hydroxyl locked in hydrous silicates). Organic matter, which may represent a few percent of the matrix, is present in insoluble and soluble form. The insoluble organic matter (IOM), which makes the majority, is dominated by aromatic units while the soluble organic matter (SOM) may comprise such molecules considered as “prebiotic” such as sugars or amino acids. What part formed (or was modified) in the interstellar medium, the disk or after accretion remains contentious.

The modal abundances of the above chondrite components vary. *Ordinary chondrites*, which make up 80% of falls, typically contain more than 80 vol% chondrules. *Enstatite chondrites* are similarly chondrule-dominated but set apart by a more reduced opaque and silicate mineralogy. Refractory inclusions are notable (a few vol %) only in *carbonaceous chondrites* which also contain less chondrules and more matrix up to 100 vol% for CI chondrites (hence the larger bulk carbon content of many of them, though others are not more C-rich than noncarbonaceous chondrites) and as such qualify as the most primitive chondrites. Some chondrites (CH, CB) genetically associated with the carbonaceous chondrites are metal-rich and hold quite distinctive (dominantly nonporphyritic) chondrules; the latter are commonly held to be, at least in part, the results of impacts, but this does not prejudice the origin of their counterparts in “mainstream” chondrites.

While chondrites have changed little since accretion, they are not entirely pristine. Heating due to ^{26}Al decay may have caused metamorphism, with recrystallization gradually blurring the individual components and diffusion erasing

the original disequilibrium of the mineral assemblage, as in many ordinary and enstatite chondrites. If the parent body incorporated water ice, its melting may have incurred aqueous alteration causing oxidation of opaque phases, hydration of originally anhydrous minerals, and precipitation of new phases (e.g., carbonates). Such was the fate of many carbonaceous chondrites. In CI chondrites such as Orgueil, aqueous alteration has destroyed almost all high-temperature components. Metamorphism and aqueous alteration are evaluated on a single petrographic (or “petrologic”) scale from 1 to 7 devised by Van Schmus and Wood (1967). Type 3 chondrites are the most pristine, while types 4–7 correspond to increasing degrees of thermal metamorphism and types 2 and 1 to increasing degrees of aqueous alteration. Metamorphism and aqueous alteration were not entirely mutually exclusive, and evidence for both may be found in the same chondrite.

Differentiated Meteorites

While chondrites escaped melting, heating had of course no reason to stop short of solidus temperatures in all planetesimals. Thus, chondritic composition protoliths which exceeded about 950 °C suffered partial melting of metals and sulfide, and only 100 °C more sufficed to cause partial melting of silicates. Some meteorites are solid residues of such partial melting and thus represent an arrested stage of the differentiation process. They are called *primitive achondrites* for they generally retain a near-chondritic (primitive) bulk chemical composition (depending on the amount of melt extracted or gained) but have essentially lost their original chondritic texture (save perhaps for very rare relict chondrules).

At temperatures above silicate melting, significant mobility of melts was possible and so the parent body could segregate different phases according to density. This is *differentiation*. Dense metallic liquids, scavenging siderophile and chalcophile elements, would congregate to form an iron core, from which the *iron* meteorites crystallized. Irons from individual planetesimal cores show a range in composition because of fractional crystallization, where early crystallized irons concentrated compatible elements (i.e., elements partitioning preferentially into the solid, e.g.,

iridium) and later solidified irons had a greater share of incompatible elements. The metal originally crystallized as meter-size *taenite* (a face-centered cubic iron-nickel alloy) crystals but these underwent subsolidus exsolution of *kamacite* (a nickel-poorer body-centered cubic iron-nickel alloy) lamellae. Upon etching a polished slab of an iron meteorite, the less acid-resistant kamacite lamellae will appear as intercrossing sets of parallel silvery bands forming so-called *Widmannstätten patterns*. Macroscopic Widmannstätten patterns, which develop only because of the slow cooling (typically 1–100 K/Ma) in planetesimal interiors, are notoriously diagnostic of extraterrestrial metal. Strictly speaking, they are well-developed only in the (majority) structural class called *octahedrites* (because the kamacite plate orientations are parallel to the faces of a regular octahedron); too nickel-poor irons are dominated by kamacite and are called *hexahedrites* while nickel-rich ones contain only microscopic kamacite spindles and are called *ataxites*. Some irons do not seem to have fractionally crystallized (or “fracrystallized” for short), retaining near solar proportions of siderophile elements, and often contain silicate inclusions. These irons (once termed “nonmagmatic,” when their igneous nature was questioned, but more appropriately called “non-fracrystallized”) may have formed as a result of a catastrophic impact, mixing a still-molten (and unfractionated) core with mantle material. An impact may have alternatively formed a local melt pool at the surface of a chondritic body which would have partly differentiated. Some fracrystallized irons contain abundant olivine inclusions and are known as *pallasites*, which may also be the result of impact, perhaps at the core-mantle boundaries of their parent bodies.

Turning attention to the rocky outer layers, partial silicate melts, typically of basaltic composition, would tend to migrate toward the surface of the differentiating parent body, building a crust enriched in incompatible lithophile elements. The differentiating parent body might temporarily host a global magma ocean (sequestering the available ^{26}Al) there. The mantle underlying the crust may still contain partial melt residues (i.e., primitive achondrites) but the other rocks, whether formed by closed-system crystallization of a melt or the

accumulation of crystals settled from a magma body, are fully magmatic (or igneous) in nature and called *evolved achondrites*. Eucrites are example basaltic or gabbroic achondrites, while diogenites feature orthopyroxenites formed in generally deeper-seated plutons. So, an intact differentiated parent body comprises an iron core and achondritic mantle and crust. Many achondrites are brecciated (such as the howardites mixing eucritic and diogenitic clasts), and mesosiderites mix eucrite-diogenite-like material with metal presumably derived from the naked iron core of some disrupted planetesimal.

Key Research Findings

Meteorite Genetics

Meteorites do not present a continuum in compositional (isotopic, chemical, and textural) space. Rather, they form discrete clusters known as *groups* which are generally believed to represent individual primary parent bodies (or a set of similar parent bodies). Indeed, although the protoplanetary disk may have produced a continuum of planetesimals, it must be remembered that the asteroid main belt hosts but a tiny portion of the original population so sampling is necessarily sparse.

Groups among chondrites are given one- or two-letter designations. For example, ordinary chondrites are subdivided into H, L, and LL groups, which stand for “high,” “low,” and “low low” iron contents (anticorrelated with FeO contents in silicates), respectively; same for EH and EL for enstatite chondrites (at least etymologically, for they may actually only differ in redox state). Carbonaceous chondrite groups are denoted with a “C” plus the initial of the type meteorite. For instance, “CM chondrites” refers to Mighei-type carbonaceous chondrites (such as Murchison). The petrologic type is usually combined with the group acronym to display the complete classification, for example, Murchison is a CM2 chondrite while Orgueil is a CI1.

Iron chemical groups are given combinations of Roman numerals (from I to IV, in order of decreasing moderately volatile element content)

and letters (sometimes combined, depending on the vicissitudes of subdivisions and recombinations over the past half century), such as IIE or IIIAB, for example. Achondrite groups are given names ending in “-ites,” usually built on the name of a type of meteorite, for example, aubrites are enstatite achondrites named after the Aubres fall in France. Many meteorites are not affiliated to any established group (whose recognition by the Nomenclature Committee requires at least five unpaired members) and are termed “ungrouped” or “anomalous,” if allowance is made for them, more than 100 primary parent bodies may be represented in our meteorite collections (Greenwood et al. 2020).

Some sets of recognized groups actually represent different lithologies of a single primary parent body, such as the isotopically similar howardites, eucrites, and diogenites, collectively referred to as the “HED” clan, which are widely believed to originate from asteroid Vesta, based on

spectroscopic correspondence with its largely basaltic crust. Accounting for chemically anomalous irons, many more iron cores than mantle or crusts seem to be sampled; this paradox is the “dunite problem.” Possibly, most irons come from a very collisional inner solar system that essentially “battered to bits” early differentiated planetesimals, with only the more durable metallic fragments surviving to the present day.

Isotopic similarity is no infallible proof of a common parent body (e.g., enstatite chondrites, aubrites, Earth, and the Moon are nearly isotopically indistinguishable) but does at least indicate provenance of a common restricted space-time section of the protoplanetary disk called a “reservoir” in cosmochemical parlance. Such affinities are depicted in Fig. 1.

On a broader scale, isotopic data show a remarkable first-order dichotomy between carbonaceous (C) and noncarbonaceous (NC) chondrites, which

Meteorites, Fig. 1 Classification of asteroidal meteorites. Petrological classes (chondrites, irons, achondrites, with indicative subdivisions) are presented in the vertical direction and groups in the horizontal direction, along with higher-order groupings (in particular the distinction between the carbonaceous (C) and non-carbonaceous (NC) superclans). *ACA* acapulcoite, *ANG* angrite, *AUB* aubrite, *BRA* brachinite, *DIO* diogenite, *EC* enstatite chondrites, *HED* howardite-eucrite-diogenite, *HOW* howardite,

Meteorites, Fig. 2 The carbonaceous/non-carbonaceous chondrite dichotomy. $\delta^{50}\text{Ti}$ and $\delta^{54}\text{Cr}$ refer to relative deviations of the $^{50}\text{Ti}/^{47}\text{Ti}$ and the $^{54}\text{Cr}/^{52}\text{Cr}$ ratios relative to a terrestrial standard. (Data from Dauphas and Schauble (2016))

also applies to differentiated meteorites, with most of them belonging to the NC *superclan* (Fig. 2). Compared to NC meteorites (and Earth), C meteorites are enriched in neutron-rich isotopes of Ti and Cr and are ^{16}O -rich (in a mass-independent way). Since refractory inclusions (abundant only in C chondrites) display such enrichments to an even higher degree, it is tempting to ascribe the difference to mere addition of refractory inclusions, but mass balance calculations require a part of the host chondrite to carry such isotopically anomalies as well. The NC and C (super)reservoirs are widely believed to represent the inner and outer regions of the solar protoplanetary disk, respectively, consistent with the present-day segregation of S and C complex asteroids, and the divide between the two (which may have been close to the snow line) might relate to Jupiter. It is somewhat paradoxical, then, that carbonaceous chondrites should be those *most* enriched in refractory inclusions believed to have formed close to the young Sun. This has motivated various astrophysical models of outward transport of solids (e.g., Jacquet 2014).

For many isotopic systems, the differences must ultimately relate to variable populations of presolar grains in the building blocks of planetesimals. Indeed, the isotopic composition of C chondrites can be often rationalized as an overabundance of a nucleosynthetic component

produced in a neutron-rich stellar environment (e.g., a supernova). One school of thought considers that “thermal processing” preferentially evaporated some presolar grains, but it is unclear how this could have favored systematically the same nucleosynthetic component for elements of very different volatilities and presumed carriers. Another possibility is that this heterogeneity was inherited from the *protosolar cloud*, that is, the molecular cloud fragment which collapsed to form the early Solar System. Transport and mixing in the disk would have diminished the primordial heterogeneity, but would not erase it entirely. Refractory inclusions, which are isotopically more anomalous and variable than bulk chondrites, would fossilize early stages in this process. Ultimately, the heterogeneity may relate to fresh inputs of stellar ejecta. ^{26}Al itself may have been introduced by the winds of a massive star, which may have triggered the gravitational collapse of the protosolar cloud.

Other isotopic variations in meteorite whole-rocks or components were acquired within the disk. Some isotopes, such as short-lived beryllium-10 (half-life: 1.5 Ma) evinced by excesses of radiogenic boron-10 in CAIs, may have been produced during irradiation by energetic solar protons. The oxygen in solids, whose original isotopic composition seems to be recorded by refractory inclusions (which coincide with the present-day solar wind, notwithstanding mass-dependent fractionation), evolved toward ^{16}O -poorer (by 5–6%) composition prior to the formation of meteorite parent bodies, apparently by isotopic exchange with isotopically heavy water of as yet uncertain origin. In addition to mass-dependent effect, mass-dependent isotopic variations (e.g., for moderately volatile elements) may reflect kinetic gas-condensate exchanges.

While much attention is nowadays given to isotopic diversity, chemical variations in the disk were greater, sometimes at a few tens of %. While chondrites were introduced above as primitive solar material, strictly speaking, only CI carbonaceous chondrites provide a good chemical match with the solar photosphere. Other carbonaceous chondrites are typically enriched in refractory elements and show a monotonic depletion of

Meteorites, Fig. 3 Major lithophile element fractionation among chondrites. Carbonaceous and non-carbonaceous chondrites form distinct trends intersecting at solar (CI) composition. (Data from Hutchison (2004) and Metzler et al. (2021))

moderately volatile elements as a function of theoretical half-condensation temperature. This latter depletion is also apparent for non-carbonaceous chondrites, which are *depleted* in refractory elements and have subsolar Mg/Si (Fig. 3). Such chemical fractionations must reflect incomplete condensation processes and aerodynamic sorting of solids (which may also have incurred metal-silicate fractionations in individual reservoirs, for example, between H, L, and LL ordinary chondrites), but such processes are poorly understood. The average composition of differentiated parent bodies is difficult to reconstruct from individual meteorites, but great depletions in moderately volatile elements, sometimes by orders of magnitude, are apparent. While formation in very hot regions of the disk has been entertained, the parent bodies may have outgassed after accretion, because of radiogenic and/or impact heating.

Applications

Meteorites are samples of small bodies of the Solar System and, as such records of the first Ma of Solar System history and “ground truth” for protoplanetary disk astrophysics. Chondritic and iron asteroids are also entertained as mining resources for metal and water.

Future Directions

Overall, meteorites still present tantalizing first-order enigmas as to the genesis of their various components or their diversity as whole rocks. This is because, as rocks, they lack geologic context, though sample-return missions contribute to reconstruct one. The interaction with astronomical observations of protostars (and astrophysical modelling) also provides a bridge toward our past 4.57 Ga ago. Primitive Solar System geology can thus still hope to find its Wegener!

Meteorites, History of

Stéphane Le Gars

Centre François Viète, Université de Nantes,
Nantes, France

History

Meteorites have been objects of reverence in many premodern cultures, for example, in North America and in Europe, when the local population believed that they had fallen from the sky (e.g., Nininger 1972). Meteoritic iron was the only source of that metal before the invention of iron smelting and the beginning of the Iron Age; early iron weapons were thus exceptionally valuable. It is at the end of the eighteenth century that meteorites obtained the status of scientific objects. In

1794, the German scientist Ernst Florens Friedrich Chladni (1756–1827) explained the result of the observational comparisons he had made among lots of “fallen stones” and made a link between these stones and the fireballs observed for a long time in the atmosphere. This first systematic work on objects that were at that time despised induced him to ascribe an extraterrestrial origin to what were soon to be called “meteorites.” His results were confirmed at the beginning of the nineteenth century by chemical analysis and the discovery of the asteroid belt between Mars and Jupiter.

Meter-Size Catastrophe

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

In a ▶ [protoplanetary disk](#), dust and gas orbit the star at different rates: gas pressure slows the revolution of the gas molecules, but not the much more massive dust particles. Therefore, the faster moving dust particles experience a headwind and a corresponding drag force due to the gas, which can lead to orbital decay for the particles. Small particles ($\sim 1\text{ }\mu\text{m}$) behave essentially like the gas and do not feel a strong headwind. Large particles ($>10\text{--}100\text{ m}$) have sufficient inertia to minimize orbital changes due to gas drag. However, at roughly 1 cm to 1 m in size, the effect of gas drag on particle orbits is the strongest. Calculations show that particles about 1 m in size feel the most gas drag, and they may spiral into their star from a distance of 1 AU so quickly that they probably cannot merge and grow fast enough to form 1 km-sized ▶ [planetesimals](#). Consequently, unless particles grow quickly through this phase, or unless particles of much bigger size are formed by collective mechanisms from smaller mass particles, the formation of planet would be difficult to explain – a potential “catastrophe” for theories of planetary formation.

Methane

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Synonyms

[CH₄](#)

Definition

Methane, CH_4 , is the simplest hydrocarbon molecule. Methane is a major component of natural gas, and is known as one of the major greenhouse gases. Both gaseous and solid methane have been detected in molecular clouds, and it has also been found in cometary comae. Methane is a major carbon species in the atmospheres of the outer planets such as ▶ [Jupiter](#) and Saturn. ▶ [Titan](#), the largest satellite of Saturn, has a dense atmosphere containing methane, and methane can form lakes on the surface of Titan.

Overview

Methane is a tetrahedral molecule, where four hydrogen atoms are covalently bound to the

central carbon atom with a bond length of 0.1087 nm and a bond angle (H–C–H) of 109.5°. Its melting point is 91 K, and its boiling point is 112 K. It is combustible and has been used as fuel. Methane hydrate, methane surrounded by water molecules forming a clathrate, has been found on the ocean floor and in permafrost since 1971, and is considered important fuel for the future.

Methane is a minor component of the Earth atmosphere, and its global average concentration was 1803 ppm in 2009, but is increasing by 5 ppm per year mainly due to human activities. Methane is known as a greenhouse effect gas together with carbon dioxide, water vapor, and nitrous oxide.

The concentration of methane in primitive Earth's atmosphere has been the subject of controversy since the mid-twentieth century. Some scientists, including Harold Urey, postulated that methane was its major component together with hydrogen and ammonia. Others, such as William Rubey, suggested that the atmosphere was less reducing and that carbon dioxide and nitrogen were its major constituents. Stanley Miller, following Urey's idea, performed in 1953 a historic spark discharge experiment in a gas mixture of methane, ammonia, hydrogen, and water. It was observed that a wide variety of organic compounds including amino acids could be easily formed from the gas mixture. A great number of experiments were further conducted using a methane-ammonia type gas mixture and a variety of energies (UV, heat, radiation, etc.) and formation of amino acids were also confirmed in them.

The scenario for the formation of Earth's atmosphere by impact degassing during heavy bombardment, suggests that methane and ammonia were not major components of the primitive atmosphere, and the formation of bioorganic compounds from the atmosphere becomes more difficult. Amino acid formation could however still have been possible if methane was present in the primitive Earth's atmosphere as a minor constituent, as seen in Titan atmosphere. Titan has a dense atmosphere (ca. 150 kPa) with a predominant portion of dinitrogen and a few percent of methane. By the action of plasma

discharge, UV and/or proton irradiation of simulated Titan atmosphere, complex organic compounds, sometimes referred to as tholins, are formed together with a wide variety of higher hydrocarbons and nitriles. The Cassini spacecraft discovered lakes on Titan surface, and the lakes should contain liquid methane and ethane. Cassini also found methane rain. Thus, Titan could have a methane cycle, in place of a water cycle as found on Earth.

Another possible environment for abiotic synthesis is submarine hydrothermal systems. In 1977, scientists diving off the coast of the Galapagos Islands, found superheated seawater erupting from the sea bottom. The fluid temperature was over 300 °C and contained reducing gases including methane, hydrogen, and hydrogen sulfide. It was postulated that abiotic reactions could have taken place using methane and other compounds in submarine hydrothermal systems. It is known that chemosynthetic microorganisms make biospheres near such environments. Chemosynthetic microorganisms include methanogens that reduces carbon dioxide to form methane and methanotrophs that oxidize methane. Thus, methane is considered an important biosignature.

Several groups have detected methane on Mars. Since methane is easily decomposed in Mars' atmosphere, discovery of methane suggested that continuous production of methane might be an evidence of life on Mars.

Methane Oxidation

Lisa Y. Stein

Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada

Keywords

Methanotroph · Methane monooxygenase · Methyl-coenzyme M reductase · Anaerobic oxidation of methane (AOM) · Anaerobic methane-oxidizing archaea (ANME) · Nitrite-driven anaerobic methane oxidation (n-DAMO) · Trace methane oxidation (TMO)

Definition

Methane oxidation is the major methane sink in the biosphere, accomplished by diverse and ubiquitous microorganisms in the bacterial and archaeal domains of life. Methane oxidation occurs from fully oxic, to hypoxic, to anoxic environments. Aerobic and intra-aerobic methane oxidation requires the methane monooxygenase enzyme (MMO) to activate methane (Ettwig et al. 2010), whereas anaerobic methane oxidation by archaea involves the reverse methanogenesis pathway powered by methyl-coenzyme M reductase (MCR) (Evans et al. 2019). Anaerobic methane oxidation can be coupled to the reduction of sulfate (Milucka et al. 2012), nitrate (Haroon et al. 2013), nitrite (Ettwig et al. 2010), and iron/manganese (Ettwig et al. 2016), uniting a multitude of biogeochemical cycles. The diversity of metabolic strategies for methane oxidizers suggests that they could thrive in extraterrestrial ecosystems where methane is sustainably produced.

Overview

Organisms

Methane is produced in any ecosystem where there is plentiful organic matter available for fermentation, followed by methanogenesis. In turn, methane oxidation is favored by microbes that can acquire methane and metabolize it as a source of both carbon and reductant to drive cellular processes. These microbes are called “methanotrophs,” literally methane eaters, and have evolved specialized pathways to generate proton motive force from methane oxidation and can assimilate single-carbon molecules into biomass.

Aerobic methanotrophs are found in the *Proteobacteria* phylum in the classes *Alphaproteobacteria* and *Gammaproteobacteria* (Bowman 2006; Webb et al. 2014) and in the *Verrucomicrobia* phylum. A primary difference between *Alpha*- and *Gammaproteobacteria* methanotrophs is that the former uses the serine pathway and the latter uses the ribulose monophosphate pathway to assimilate formaldehyde. Alternatively, methanotrophs in the *Verrucomicrobia* phylum fix carbon dioxide using the Calvin-Benson-Bassham (CBB) cycle (Khadem et al. 2012) and can grow chemolithotrophically from hydrogen oxidation in addition to growing on methane (Carere et al. 2017). Some *Alphaproteobacteria* methanotrophs have metabolic flexibility beyond methane and can grow on multicarbon compounds (Tamas et al. 2014).

The anaerobic methanotrophs include both bacteria in the NC10 phylum (Ettwig et al. 2010) and archaea in the Euryarchaeota phylum (Evans et al. 2019). The NC10 bacteria, typified by the species *Ca. ‘Methylomirabilis oxyfera,’* perform “intra-aerobic methane oxidation” wherein methane is oxidized at the expense of nitrite reduction, a process that produces O₂ from the dissimilation of the metabolic intermediate, nitric oxide. The archaeal anaerobic methane oxidizers (ANME) perform reverse methanogenesis and consume methane as a carbon/energy source. Some can also oxidize multicarbon compounds in addition to methane (Evans et al. 2019).

Certain genera of *Gammaproteobacteria* methanotrophs can grow under extremely

hypoxic conditions by oxidizing methane at the expense of nitrate (Kits et al. 2015) or by fermenting formaldehyde using central carbon pathways (Kalyuzhnaya et al. 2013). These particular methanotrophs have systems to scavenge oxygen at extremely low concentrations and are not considered true anaerobes, but can be plentiful in environments marked by extreme hypoxia to anoxia (Chistoserdova and Kalyuzhnaya 2018).

Enzymology

Aerobic methane oxidation in *Proteobacteria* and *Verrucomicrobia* relies on a series of enzymes that transform methane sequentially into methanol, formaldehyde, formate, and carbon dioxide. The key enzyme in this process is methane monooxygenase (MMO), which has both a soluble cytoplasmic and a particulate membrane-bound form that share an evolutionary history (Osborne and Haritos 2018). There are also two forms of methanol dehydrogenase (MDH), a calcium-dependent (MxaF) and a lanthanum-dependent (XoxF) form (Chistoserdova and Kalyuzhnaya 2018). XoxF is one of very few enzymes known to require rare Earth elements for its active site. The tetrahydromethanopterin-/methanofuran (H₄MPT/MF)-linked pathway that facilitates conversion of formaldehyde to formate is ancient and links all domains of life (Chistoserdova and Kalyuzhnaya 2018). The evolutionary history of this formaldehyde-activating pathway suggests that metabolism of C1 molecules originated very early in life history. Formate dehydrogenase is the final enzyme in the methane oxidation pathway that produces CO₂ and intracellular reductant (NADH). Carbon assimilation by proteobacterial methanotrophs proceeds at the level of formaldehyde via the serine or ribulose monophosphate pathways (Bowman 2006; Webb et al. 2014).

The enzymology of anaerobic methane oxidation by NC10 bacteria is the same as that for the aerobic methanotrophs with the exception of nitrite reductase and nitric oxide dismutase (NOD) enzymes that terminate the electron transport chain or produce O₂ for methane oxidation, respectively (Ettwig et al. 2010). NC10 bacteria,

like the *Verrucomicrobia*, fix CO₂ via the CBB pathway (Rasigraf et al. 2014). Anaerobic methane oxidation by ANME archaea relies on the reversibility of the key methanogenesis enzyme, methyl-coenzyme M reductase (Mcr), and can be coupled to the reduction of many molecules including nitrate, iron, manganese, and sulfate (Timmers et al. 2017). Some pure cultures of methanogenic archaea can oxidize small amounts of methane, but only during net methane production in a process called “trace methane oxidation (TMO)” (Timmers et al. 2017). TMO does not allow for energy conservation and is likely caused by a reverse flux of substrate by individual enzymes within the methanogenic pathway.

Environments and Astrobiology

While aerobic methanotrophs are pervasive in nearly every ecosystem with ready access to oxygen and methane, anaerobic methanotrophs and those that grow under extreme hypoxia are most relevant for understanding the origins of methanotrophy on Earth and the possibility for similar metabolism to exist on extraterrestrial bodies. Due to common nomenclature, ANME archaea have been designated as “reverse methanogens,” while in reality there is evidence that these microbes initially arose as anaerobic methanotrophs and not as methanogens (Russell and Nitschke 2017). The speculative model involves a “denitrifying methanotrophic acetogenic pathway” whereby methane combines with formate or CO to generate acetate, a common product of ancient carbon fixation pathways. In the model, reduction of nitrate/nitrite to NO would activate methane oxidation and also provide assimilable nitrogen. This series of reactions can be coupled to serpentinization reactions that generate formate, H₂, and reductant at hydrothermal vents, a favored environment for modeling the origins of life.

Aside from ANME archaea, methanotrophs with MMO enzymes in the *Proteobacteria*, *Verrucomicrobia*, and NC10 phyla also thrive under hypoxic to anoxic environments by tightly coupling oxygen production and consumption (Chistoserdova and Kalyuzhnaya 2018). In an astrobiology context, both perchlorate and

methane have been detected on Mars as early as the Viking Lander experiments, although the source and sustainability of these molecules are still questioned (Levin and Straat 2016). If perchlorate and methane were continuously generated and available in the Martian subsurface, microorganisms could conceivably reduce perchlorate to generate O₂, which in turn could be scavenged by methanotrophs to activate methane. Indeed, the finding of methanotrophs with oxygen-dependent enzymology thriving in anoxic environments on Earth suggests that cryptic oxygen cycling is a normal part of ecosystem function (Chistoserdova and Kalyuzhnaya 2018). Certainly, sustainable sources of other essential elements including nitrogen, sulfur, phosphorous, transition metals, etc. were necessary for establishing viable cellular life on Earth and are likely also necessary for diversifying enzymology and stabilizing cellular life in other planetary contexts. However, biological methane oxidation as a key catabolic pathway remains a strong candidate for life on other planets as well as for origins of life on Earth.

Summary

Biological methane oxidation is an ancient metabolism that is performed by both *Bacteria* and *Archaea* from fully oxic to anoxic ecosystems. Methanotrophic microorganisms evolved specialized pathways to activate methane and use it as both a carbon and energy source. Two enzymatic mechanisms for methane activation have been identified: methane monooxygenase and methyl-coenzyme M reductase. The ability of aerobic methanotrophs to tightly couple oxygen consumption with oxygen generation, as well as the diversity of electron acceptors that connect to methane oxidation, suggests that this metabolism is adaptive to a wide range of ecosystems, possibly including extraterrestrial bodies.

¹Laboratoire d’Astrophysique de Bordeaux, Université de Bordeaux, Pessac, France

²Institut de Recherche en Astrophysique et Planétologie, Université de Toulouse, Toulouse, France

Synonyms

CH₃SH; Mercaptomethane; Methyl mercaptan; Thiomethanol

Chemical Formula

CH₃SH

Definition

Methanethiol (its IUPAC official name) is a colorless gas under standard temperature and pressure, becoming liquid at 6 °C. It is the simplest thiol (thiols are analogs to alcohols, with an SH group replacing OH). Methanethiol has a strong rotten cabbage smell, so that some is added to natural gas to ease leak detection. It is produced by decaying organic matter in marshes and by decomposition of an algal metabolite (DMSP, dimethyl sulfonio propionate). It is the main sulfur source of some marine bacteria and a possible substrate for methanogenesis. In prebiotic chemistry, its presence allows for the synthesis of the S-bearing amino acid methionine in Urey-Miller experiments (Miller 1974). Methanethiol has been found in interstellar space.

History

Methanethiol was first detected in the interstellar medium towards the high-mass star-forming region Sgr B2 close to the Galactic center by Linke et al. (1979). Since then, it was found towards other astrophysical objects including the high-mass star-forming regions G327.3–0.6 (Gibb et al. 2000), Orion KL (Kolesníková et al. 2014), IRAS 16547–4247 (Zapata et al. 2015), and G31.41+0.31 (Gorai et al. 2021), the low-mass protostar IRAS16293–2422 (Majumdar et al. 2016) and the dense cores B1-b (Cernicharo et al. 2012) and L483 (Agúndez et al. 2019). Methanethiol was also detected in the coma of comet 67P/Churyumov–Gerasimenko in the framework of the Rosetta mission (Calmonte et al. 2016).

Methanimine (CH₂NH)

William M. Irvine
Department of Astronomy, University of
Massachusetts Amherst, Lederle Graduate
Research Tower B 619E, Amherst, MA, USA

Keywords

Glycine · Interstellar · Molecules

Synonyms

[Methylenimine](#)

Chemical Formula

CH₂NH

Definition

The organic molecule methanimine is not terribly stable under terrestrial conditions, being a minor equilibrium product of the reaction of ammonia and formaldehyde. It has been suggested as a possible precursor to the amino acid glycine in some astrophysical settings (e.g., Godfrey et al. 1973).

Overview

Methanimine was one of the first relatively complex organic molecules detected in the interstellar medium (Godfrey et al. 1973), towards the Galactic Center molecular cloud SgrB2. It has subsequently been found in several “hot core” sources, interstellar molecular clouds where massive stars are forming (Dickens et al. 1997). Methanimine may also be present in the atmosphere of Saturn’s satellite Titan (Vuitton et al. 2006).

Keywords

Archaea · Extremophiles · Anaerobic · Methane · Nickel · Respiration

Acronyms

MCR Methyl coenzyme M reductase

Definition

Methanogenesis is an anaerobic respiration leading to the biological production of methane.

Chemical Formulas

Hydrogenotrophic methanogenesis:

$$\Delta G^\infty = -135.6 \text{ KJ mol}^{-1} \text{ methane}$$

Methylotrophic methanogenesis:

$$\Delta G^\infty = -112.5 \text{ KJ mol}^{-1} \text{ methane}$$

Aceticlastic methanogenesis:

$$\Delta G^\infty = -31.0 \text{ KJ mol}^{-1} \text{ methane}$$

(1)

History

The discovery of biological methane production as flammable marsh gas dates back to the Italian physicist Alessandro Volta in the mid-1700s. Methanogenic archaea were first isolated in the 1930–1940s, but not recognized as Archaea until the late 1970s (Balch et al. 1979). Elucidation of the pathway of methanogenesis was achieved during the 1980–1990s. In the twenty-first century, gene sequencing from environmental DNA revealed a much wider diversity of methanogens than previously recognized, much of which remains uncultivated.

Overview

Methanogenesis, or biological production of methane via anaerobic respiration, accounts for 70% of the 500–600 tera-grams of methane emitted to Earth's atmosphere each year (Lyu et al. 2018). To date, all the methanogens discovered so far are: (1) strict anaerobes with metal-rich enzymes that are highly sensitive to molecular oxygen; (2) obligate methanogens that only grow while making methane, and (3) *Archaea* that are evolutionarily very distinct from the more familiar *Bacteria* (Whitman et al. 2014). Methanogens are commonly considered the bottom of the proverbial anaerobic “food chain” and use the poor electron acceptor carbon dioxide. They harvest the scarce energy left once complex carbon molecules have been broken down to simpler organics like acetate and methylated compounds, or they use hydrogen gas, formate, simple alcohols, or carbon monoxide to reduce carbon dioxide to methane (see [Chemical Formulas](#)). Therefore, methanogenesis only dominates in anoxic ecosystems when better electron acceptors (e.g., oxygen, nitrate, sulfate, and oxidized metals) become depleted. Methanogenic habitats can be natural (e.g., wetlands, sediments, soils, gastrointestinal tracts of animals) or created by humans (e.g., wastewaters, rice paddies, livestock ruminants, and the lower intestinal track in humans).

Energetics of Methanogenic Metabolisms

Methanogens are named according to their

substrate. Aceticlastic methanogens use acetate, splitting it into carbon dioxide and methane. Methylothermophilic methanogens use methanol or other methyl-containing compounds as the carbon donor. Often the methyl group is reduced to methane with hydrogen, but some methylothermophiles can also oxidize the methyl groups to reduce the remaining methyl groups in a process called disproportionation. Hydrogenotrophic methanogens often use hydrogen gas to reduce carbon dioxide to methane, but some can use other electron donors such as formate and simple alcohols such as isopropanol and ethanol. However, they have a very limited capacity to oxidize complex organic molecules, and isopropanol is only oxidized to acetone and ethanol is only oxidized to acetate.

The energy yield of cellular respiratory processes can be predicted from the magnitude of the free energy change; the more negative the ΔG° value, the higher the energy and growth yield. At standard state conditions, hydrogenotrophic methanogenesis is predicted to yield the highest change in free energy (see [Chemical Formulas](#)). However, the actual $\Delta G'$ for hydrogenotrophic methanogenesis is typically much lower than the standard state value because $\Delta G'$ varies with the fourth power of hydrogen concentration, and hydrogen concentrations are often extremely low in natural environments. Thus, methylothermophilic methanogenesis is often more energetically favorable than hydrogenotrophic methanogenesis under conditions found in the environment. Aceticlastic methanogenesis is typically the least energetically favorable of the three types (Lyu et al. 2018). Unlike many other microbes, methanogens cannot grow via fermentation or using alternative electron acceptors.

Ecology of Methanogens Hydrogenotrophic methanogens are responsible for approximately a third of methane emissions, and aceticlastic methanogens are responsible for the other two-thirds (Angle et al. 2017; Lyu et al. 2018). Importantly, hydrogenotrophic methanogenesis also maintains the low concentrations of hydrogen necessary to allow the complete degradation of complex organic compounds to acetate and

carbon dioxide in a process called interspecies hydrogen transfer. Hydrogenotrophic methanogenesis dominates in ecosystems where hydrogen can accumulate due to geothermal gaseous sources (e.g., hydrothermal vents; 3% of global methane emissions) and in the digestive tracts of animals such as livestock (25% global emissions) and termites (4% global emissions) where fermentation by other microorganisms provides a hydrogen source and organic acids are assimilated by the animal. Aceticlastic methanogens dominate in anaerobic digestors (sewage treatment, 6% global emissions), rice fields (15% global emissions), and wetlands (33% global emissions). Methylothermophilic methanogenesis is a minor source of global methane emissions and occurs primarily in marine (4% global emissions) and hypersaline environments where the osmolytes betaine and dimethylsulfoniopropionate are abundant sources of methyl-containing compounds (Lyu et al. 2018). Coal bed methane is also produced by methylothermophilic methanogens from methoxylated aromatic compounds (Mayumi et al. 2016).

Biochemistry of Methanogenesis In contrast to the simplicity of the chemical reactions (see [Chemical Formulas](#)), the biochemical complexity of methanogenesis is comparable to that of photosynthesis (DiMarco et al. 1990; Thauer et al. 2008). Depending on the substrate, up to seven unusual coenzymes participate in the pathway, and about 200 genes are required to synthesize the enzymes and coenzymes for methanogenesis. Abundant metals, particularly iron, nickel, cobalt, and molybdenum or tungsten, are required for methanogenesis (Glass and Orphan 2012). Some methanogens also use selenium to make selenocysteine, the 21st amino acid (Rother and Krzycki 2010). All methanogenic pathways have in common the last enzyme, methyl coenzyme M reductase (MCR), and the *mcrA* gene is widely used as a molecular marker for methanogens in the environment. MCR uses the thiol on coenzyme B to reduce methylcoenzyme M, forming the heterodisulfide of coenzyme M and coenzyme B and methane. Heterodisulfide is converted back to coenzymes M and B by the iron-sulfur protein

heterodisulfide reductase. MCR contains the unique nickel-porphyrin coenzyme F₄₃₀, which has an extremely low mid-point potential (−650 mV) and is therefore extremely oxygen-sensitive. Methanogens with the acetoclastic pathway use cytochromes for electron transfer and proton pumps for ATP synthesis, while hydrogenotrophic methanogens use flavin-based electron bifurcation and sodium pumps for ATP synthesis (Lyu et al. 2018; Thauer et al. 2008). Acetoclastic methanogens require activation of acetate to acetyl-CoA by ATP prior to splitting it into carbonyl and methyl groups. Methylophilic methanogens use cobamide-containing methyltransferases to transfer the methyl group to methylcoenzyme M. Some of these methyltransferases use the 22nd amino acid, pyrrolysine (Rother and Krzycki 2010).

Taxonomy of Methanogenesis Historically, methanogens were classified in the *Euryarchaeota* phylum of the *Archaea*. However, recent analyses of the genomes of pure cultures and metagenome assembled genomes, or MAGs, from environmental DNA indicate that methanogenesis is widely distributed among many phyla of *Archaea*. These results are consistent with the ancient origin of methanogenesis (see below) and the variety of biochemical pathways of methanogenesis. All methanogenic archaea isolated in pure culture appear to belong to one of three phyla. The first phylum *Methanobacteriota* contains three out of eight of the currently known orders of cultured methanogens: *Methanobacteriales*, *Methanopyrales*, and *Methanococcales*. All are hydrogenotrophs and related to the nonmethanogenic thermophilic heterotrophs *Thermococcales*. The cell walls of *Methanobacteriales* and *Methanopyrales* contain pseudomurien, a peptidoglycan similar to that in bacteria. These diverse taxa include *Methanobrevibacter*, the methanogen common in the gastrointestinal tract of humans and many animals, as well as the hyperthermophiles *Methanothermus* and *Methanopyrus* from hydrothermal vents. The *Methanococcales* contains mesophiles, thermophiles, and hyperthermophiles isolated from marine environments, and includes *Methanococcus*, one of the two methanogenic genera with a well-developed genetic system.

Four of the remaining orders of cultured methanogens (*Methanosarcinales*, *Methanocellales*, *Methanonatronarchaeales*, *Methanomicrobiales*) all belong to the phylum *Halobacteriota* of more metabolically diverse methanogens as well as non-methanogens including extremely halophilic *Halobacteria* and sulfate-reducing *Archaeoglobales* (Lyu et al. 2018). Hydrogenotrophic methanogenesis is present in all methanogenic orders in the second phylum except *Methanonatronarchaeales*, which are methylotrophic. Acetoclastic methanogenesis is only found in *Methanosarcinales*, which includes *Methanosarcina*, the other methanogen with a well-developed genetic system. *Methanosarcina* spp. are unusual in that they can utilize all three classes of methanogenic substrates: hydrogen, acetate, and methyl-compounds. *Methanohalobium*, an extremely halophilic methylotroph, is also a member of the *Methanosarcinales* order. The *Methanosarcinales* are also closely related to taxa that can anaerobically oxidize methane (ANME-2 clade) but have never been grown in pure culture. The *Methanonatronarchaeales* order contains extremely halophilic methylotrophs, but it is specifically related to the non-methanogenic *Halobacteria*. The *Methanocellales* order includes hydrogenotrophic methanogens common in rice paddy soil that are oxygen tolerant as well as psychrophilic permafrost methanogens. The *Methanomicrobiales* includes a wide variety of hydrogenotrophic methanogens common in bioreactors, fresh water, and brackish water. Lastly, the *Methanomassiliicoccales* are the only order of methanogens in the phylum *Thermoplasmata*. These obligate methylotrophs are common in the gastrointestinal tracts of ruminants and other mammals as well as anaerobic sediments.

Genes encoding *mcrA* have also been discovered in genomes of the uncultivated archaeal of the phylum *Bathyarchaeota* (Evans et al. 2015), *Verstraetearchaeota* (Vanwonterghem et al. 2016), as well as other archaea genomes. In some cases, there is little evidence for the metabolic function of these genes (see Evans et al 2019 for a review), suggesting that the biochemistry of methanogenesis may be more complex than currently understood.

year freeze and thaw cycles like those on Mars (Mickol et al. 2018). *Methanothermococcus okinawensis* (*Methanococcales*) endures high pressures up to 50 bar, similar to those of Enceladus, and also persists in the presence of acetylene, a methanogen inhibitor (Taubner et al. 2018). *Methanosarcina barkeri* (*Methanosarcinales*) can survive ultra-low pressures (6 mbar), desiccation, and regolith similar to the Martian subsurface (Kral and Altheide 2013). Salt tolerance is dependent on the type of methanogenesis, due to the energy requirements for salt tolerance via biosynthesis of organic osmolytes or pumping salt for osmotic balance (see refs in Enzmann et al. 2018). Therefore, methylotrophic methanogens tend to be capable of surviving at much higher salinities than hydrogenotrophic and acetoclastic methanogens; *Methanonatronarchaeum thermophilum* (*Methanonatronarchaeales*) grows optimally at 4 M sodium using a salt-in strategy (Sorokin et al. 2017).

Other Biological Methane Sources In addition to methanogenic archaea, there are several other minor sources of biogenic methanogenesis that are uncoupled to energy conservation and occur in both oxygenated and anoxic environments. The finding of methanogenesis in the presence of oxygen has been referred to as the “methane paradox” because methanogenesis is otherwise limited to strict anaerobes. The best studied pathway of aerobic methane production is demethylation of methylphosphonates during phosphorus acquisition by heterotrophic bacteria. Filamentous and unicellular cyanobacteria cultures have been reported to produce methane in the presence of oxygen, although the pathway and biochemical mechanism for this process remains unknown (Bizic-Ionescu et al. 2018). Likewise, the bacterium *Acidovorax* uses a pyridoxal phosphate-dependent enzyme to generate ammonia and methane from methylamine (Wang et al. 2021). “Mini-methane producers” are fermentative bacteria that form methylcobamides as intermediates in their metabolism. Exposure of methylcobamides to light releases small amounts of methane. Lastly, most living organisms produce small amounts of methane upon exposure to oxidative stress (Ernst et al. 2022).

More Information For more complete coverage of the ecology, physiology, biochemistry and genetics of methanogenesis, readers are referred to Ferry (2012). For a database of methanogen growth conditions, readers are referred to Michał et al. (2018). For more information on methanogens in the context of astrobiology and geochemistry, readers are referred to Taubner et al. (2015) and Strapoć (2017), respectively.

Methanogenic Archaea

► Methanogens

Methanogens

José Luis Sanz
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Keywords

Anaerobic respiration · Archaea ·
Euryarchaea · Hydrogen · Methane

Synonyms

Methanobacteria; Methanogenic archaea

Definition

Methanogens are ► [microorganisms](#) whose metabolism generates ► [methane](#). All methanogenic organisms belong to the Domain ► [Archaea](#), phylum ► [Euryarchaeota](#). They are very diverse, morphologically (rods, filaments, cocci, sarcina among others) as well as phylogenetically: they are distributed in four Classes and five Orders: *Methanobacteriales*, *Methanococcales*, *Methanomicrobiales*, *Methanosarcinales*, and *Methanopyrales*. Methanogenic archaea, also referred to as methanobacteria, are the living beings most sensitive to oxygen (see ► [Anaerobe](#)), which is why they only develop in anaerobic and reducing environments (with redox potentials below -200 mV). Despite this limitation, their ecological niches are widely distributed: aquatic sediments (marshes, swamps), stagnant soil (peat bogs, ricefields), marine geothermal vents, the digestive tract of certain animals (ruminants or termites), sludge or wastewater digestors, etc.

Overview

Methanogens derive energy exclusively through the production of ► [methane](#) (a process known as methanogenesis). Methanogenesis constitutes the last step in the degradation/mineralization of organic matter in the absence of oxygen, an essential link in the carbon cycle. There are a few substrates for methanogenesis. All methanogenic Archaea (with only one exception) are able to reduce CO_2 with H_2 forming CH_4 (hydrogenotrophic methanogenesis), fixing CO_2 by the carbon monoxide pathway to synthesize their biomass. They are, therefore, chemolithoautotrophs. Many, but not all, hydrogenotrophic species can alternatively use formic acid. Another substrate that can be converted into methane is acetate (acetoclastic methanogenesis). Even

though only two genera, *Methanosarcina* and *Methanosaeta*, are acetoclastic methanogens, they are of great importance, which is reflected in the fact that two-thirds of the methane produced from complex organic matter comes from acetate. Certain members of *Methanomicrobia* can use C1-compounds (methanol or methylamines), but their relevance in the environment anaerobic full-scale digestors is limited.

Many of the ► [coenzymes](#) involved in methanogenesis are present exclusively in methanogens. Some, like the electron transporter F420, emit blue-green fluorescent light, which is useful for identifying methanogens by fluorescence microscopy. Others are involved in the final step of all methanogenesis reactions (conversion of methyl groups into methane). Coenzyme M ($\text{HS} - \text{CH}_2 - \text{CH}_2 - \text{SO}_3^-$) is among these and it is present exclusively in these organisms, which is why an analog of this coenzyme (BESA: bromo-ethanesulfonic acid) is used to specifically inhibit methanogenesis. From an energetic point of view, methanogenesis is a very inefficient process, generating only one ATP per mole of methane produced. The yield is therefore very small (only 2% of fixed CO_2 becomes biomass), and the generation times of methanogens are long (1–7 days in optimum conditions). Both of these characteristics make methanogenesis a key step in anaerobic digestion. This is of particular relevance in anaerobic treatment of wastewaters and in biomethanization processes. Although methane can be produced abiotically, 80% of the Earth methane is biologically produced by methanogens. Methanogenesis is of astrobiological interest as a unique and very ancient mode of energy conservation and especially after the recent detection of methane in the Mars atmosphere.

Methanoic Acid

- [Formic Acid](#)

Methanol

Kensei Kobayashi
Yokohama National University, Tokiwadai,
Hodogayaku, Yokohama, Japan

Synonyms

[Methyl alcohol](#)

Definition

Methanol is the simplest ► [alcohol](#), with the structural formula CH_3OH . The International Union of Pure and Applied Chemistry (IUPAC) recommends using the term methanol rather than methyl alcohol. Methanol is a colorless, volatile, and flammable liquid under standard conditions. Its melting and boiling point are $-97.8\text{ }^\circ\text{C}$ and $64.7\text{ }^\circ\text{C}$, respectively. It is a product of anaerobic metabolism of certain groups of bacteria and of the abiotic reduction of carbon monoxide with hydrogen. It is toxic to humans and other organisms since it is converted in vivo to formic acid, which many organisms have trouble metabolizing. Methanol is widely distributed in interstellar space, where it was identified in 1970. It is particularly abundant in star-forming regions such as ► [hot cores](#) and ► [hot corinos](#). Methanol has also been identified in comets. Methanol has been used as one of the carbon sources in simulated ► [interstellar ices](#), and amino acids are formed by irradiation with charged particles or ultraviolet light in the presence of a nitrogen source such as ammonia.

Methanophiles

- [Methanotroph](#)

Methanotroph

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Methanophiles](#)

Definition

Methanotrophs are organisms which are able to obtain energy by oxidizing ► [methane](#) (CH₄). Methane, found widely in nature, is produced in strict anaerobic conditions by methanogenic Archaea (see ► [Methanogens](#)). It is the main gas in anoxic muds, marshes, lakes, rice paddies, and landfill. Methane is the major constituent of natural gas and is also present in many coal formations. It can be used as an electron donor by methanotrophic bacteria. Methanotrophs can also use other one carbon compounds as a source of energy and carbon. Most of the known methanotrophs are aerobic, although, recently, methanotrophic activities in anoxic environments have been detected. All methanotrophs possess a specific enzyme, methane monooxygenase, which can insert an oxygen atom into the methane molecule generating methanol. The oxygen requirement for the oxygenation of methane explains their obligate aerobic character. The anoxic oxidation of methane requires a consortium of methanotrophic and sulfate reducing bacteria. Methanotrophs are widespread in both aquatic and terrestrial environments and are found wherever stable sources of methane are present. They play an important role in the carbon cycle.

Methionine

Kensei Kobayashi
Yokohama National University, Tokiwadai,
Hodogayaku, Yokohama, Japan

Definition

Methionine is a sulfur-containing ► [amino acid](#) with the side chain –CH₂CH₂SCH₃. Among the 20 protein amino acids, only methionine and ► [cysteine](#) have ► [sulfur](#). Its three-letter symbol is Met, and its one-letter symbol is M. The molecular weight of methionine is 149.21, and its isoelectric point (pI) is 5.74. In the standard genetic code table, only one codon AUG corresponds to methionine, and this codon is also an initiation codon. Eukaryotes and archaea, therefore, synthesize all their ► [proteins](#) with methionine at N-terminal (the amino acid with free –NH₂ group at the end of proteins). Most of N terminal methionine are removed after the translation processes. Methionine is an essential amino acid for humans.

Chemical Formula

CH₃OCH₂OH

Definition

Methoxymethanol (CH₃OCH₂OH) is an interstellar complex organic molecule and alcohol first detected in Atacama Large Millimeter/submillimeter Array (ALMA) observations of the high-mass star-forming region NGC 6334I. On Earth, this organic compound is mostly used as a solvent.

History

The only reported detection of methoxymethanol was by McGuire et al. ([2017](#)) in ALMA observations of the high-mass star-forming region NGC 6334I using ALMA observations at 1 mm. The primary formation mechanism was hypothesized to be through the reaction of methanol (CH₃OH), photodissociation product radicals methoxy

(CH₃O), and hydroxymethyl (CH₂OH). Chemical models using the magickal code (Garrod 2013) underproduced methoxymethanol, however, by more than five orders of magnitude. Several additional formation pathways were suggested, including O(¹D) insertion reactions (Bergner et al. 2017), cosmic-ray driven chemistry (Shingledecker and Herbst 2018; Zhu et al. 2019), and photochemistry product of condensed methanol (Schneider et al. 2019).

Methyl Acetate (CH₃COOCH₃)

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Synonyms

CH₃COOCH₃; [Methyl ethanoate](#)

Definition

Under standard laboratory conditions methyl acetate is a flammable liquid that is weakly polar; it is used as a solvent in some glues and related products.

History

Methyl acetate is one of the larger organic molecules detected by radio astronomers in hot cores, regions of the interstellar medium where massive stars are forming. Its isomer ► [ethyl formate](#) has also been found in ► [hot cores](#) (Tercero et al. 2013). Formation of such molecular species is thought to involve both reactions on or in the icy mantles of ► [interstellar dust](#) grains and gas phase bimolecular reactions.

Methyl Formate (HCOOCH₃)

Didier Despois
Laboratoire d'Astrophysique de Bordeaux,
CNRS-Universite de Bordeaux, Bordeaux,
France

Synonyms

[Formic acid methyl ester](#); [HCOOCH₃](#); [Methyl methanoate](#)

Definition

Methyl formate is the simplest ester and the condensation product of methanol and formic acid. It is liquid under standard pressure between $-100\text{ }^{\circ}\text{C}$ and $32\text{ }^{\circ}\text{C}$. It is a very volatile, highly flammable, and harmful compound. It is used as an insecticide and has been used formerly in refrigeration. It has been detected in the interstellar medium, where it is more abundant than its two ► [isomers](#), ► [acetic acid](#) CH₃COOH and ► [glycolaldehyde](#) CH₂OHCHO. It is one of the largest organic molecules detected in comet Hale-Bopp.

History

Brown et al. (1975) detected methyl formate in emission in the spectrum of the Galactic Center source Sagittarius B2. Several emission lines previously assigned to rotationally distorted methane in the Orion molecular cloud were correctly assigned to methyl formate by Ellder et al. (1980), from which it became apparent that the millimeter-wavelength spectrum of molecular clouds typically contain a multitude of methyl formate rotational transitions. The detection of methyl formate in comet C/1995 O1 (Hale-Bopp) was reported by Bockelée-Morvan et al. (2000).

Methyl Radical (CH₃)

William M. Irvine
Department of Astronomy,
University of Massachusetts,
Amherst, MA, USA

Synonyms

CH₃

Definition

The methyl radical CH₃ is stable enough to be observable under laboratory conditions in a dilute gas, although it readily dimerizes to ethane. It is an important intermediary in gas-phase interstellar chemistry. The incorporation of a methyl group, –CH₃, into organic compounds can have fundamental biological effects.

History

The CH₃ radical was detected in interstellar molecular clouds at wavelengths of about 16 microns using the Infrared Space Observatory (Feuchtgruber et al. 2000). It is also present in planetary/satellite atmospheres such as that of Titan (Luspay-Kuti et al. 2016).

Methyl Triacetylene (CH₃C₆H)

William M. Irvine
Department of Astronomy,
University of Massachusetts,
Amherst, MA, USA

Chemical Formula

CH₃C₆H

Definition

Methyl triacetylene is the heaviest methyl polyne (organic molecule with two or more sets of alternating single and triple bonds) thus far detected by radio astronomers in interstellar molecular clouds.

History

Methyl triacetylene joins a number of other carbon chain molecules identified in interstellar molecular clouds or the envelopes of carbon stars. These include nitriles up to HC₈CN, methyl polyynes, bare carbon chains up to C₅, radicals up to C₈H and the corresponding anions, and related species such as C₄Si, C₃O, and C₃S (see ► [“Molecules in Space,”](#) where references to many initial detections are given). Polyacetylenes such as HC₆H are also present, but, since their symmetry precludes a permanent electric dipole moment and hence pure rotational transitions accessible to radio astronomers, they have been observed through their vibrational transitions in the infrared.

Methylamine (CH₃NH₂)

William M. Irvine

Department of Astronomy, University of
Massachusetts Amherst, Lederle Graduate
Research Tower B 619E, Amherst, MA, USA

Keywords

Amino acid · Interstellar · Molecules

Synonyms

[Aminomethane](#); [Methanamine](#); [Methyl Amine](#)

Chemical Formula

CH₃NH₂

Definition

Methylamine (IUPAC names aminomethane or methanamine) is the simplest primary amine. At standard temperature and pressure, it is a colorless gas, with the liquid boiling at $-6.5\text{ }^{\circ}\text{C}$ at 1 atm. It has a fishy odor resembling that of ammonia, not surprisingly since it is derived from ammonia by replacing one hydrogen atom by a methyl group (CH₃).

Overview

Methylamine is a possible precursor to the amino acid glycine (e.g., Halfen et al. 2013) as well as various N-methyl amino acids which are sometimes detected in meteorites or laboratory simulations of prebiotic chemistry. The rotational spectrum of methylamine is complex, since it is an asymmetric top with two large amplitude internal motions: methyl group torsion and inversion of the amine hydrogens (see Spectroscopy, Rotational (Radioastronomy)). Nonetheless, it was one of the first relatively complex organic molecules

detected in the interstellar medium (Kaifu et al. 1974), towards the Galactic Center molecular cloud SgrB2.

Methyldidyne (CH)

William M. Irvine
Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

[CH](#)

Definition

The diatomic radical CH (methyldidyne), containing carbon and hydrogen, was one of the first interstellar molecules to be identified, in 1937 by T. Dunham and also by P. Swings and L. Rosenfeld. It is widespread in the diffuse ► [interstellar medium](#), where it produces absorption lines in the visible spectrum of background stars. It is an important intermediary in the production and destruction of interstellar organic molecules. Methyldidyne is also present in the coma (atmosphere) of ► [comets](#), where it is presumably a photodissociation product of organic molecules sublimating from the cometary nucleus.

History

After the first detection of the interstellar OH radical by radio astronomers in 1963, several groups looked for radio emission from interstellar CH. The search was difficult, however, because no laboratory measurements of the lowest frequency transitions was available, and theoretical predictions of the relevant frequencies were not very accurate. Radio astronomers at the Onsala Space Observatory in Sweden, led by Director Olof Rydbeck, succeeded in 1973 after a special maser receiver designed specifically for the search was built at the Chalmers Institute of Technology for use at the Observatory. Subsequently, CH emission has been detected in many interstellar molecular clouds.

More recently, submillimeter observations of CH with the - > Herschel Space Observatory and the Stratospheric Observatory for Infrared Astronomy (SOFIA) have allowed the CH abundance to be probed in different types of regions, suggesting that CH can be widely used as a proxy to estimate the molecular hydrogen (H₂) abundance (e.g., Sheffer et al. 2008; Morris et al. 2016; Wiesemeyer et al. 2018).

Micelle

David Deamer
Department of Chemistry, University of California, Santa Cruz, Santa Cruz, CA, USA

Definition

Micelles are self-assembled aggregates of amphiphilic molecules such as soaps, surfactants, and detergents. These compounds are called amphiphiles because each molecule consists of a

hydrophobic hydrocarbon chain with a hydrophilic polar or ionic head group such as hydroxyl, carboxylate, phosphate, or sulfate at one end. Amphiphiles exist in solution as individual molecules, but at a certain concentration (the critical micelle concentration, or cmc), they assemble into micelles that typically contain a few hundred molecules. Micelles in aqueous phases have hydrocarbon chains directed inward while hydrophilic head groups line the surface. The formation of micelles is one of the simplest examples of a ► [self-assembly](#) process in an aqueous medium.

Micro-Monte-Carlo Models

Eric Herbst

University of Virginia, Charlottesville, VA, USA

Definition

In a microscopic Monte Carlo model, when used for grain chemistry, the positions of each atom or molecule on the grain mantle can be followed. Thus, for an ice mantle consisting of 50 monolayers, the approach will follow all of the atoms and molecules as well as unoccupied sites for each of the 50 monolayers. In the simplest approach, each monolayer is modeled as a rectangular grid of potential wells in lattice sites with or without occupation. The atoms or molecules move from lattice well to well and possibly react when they land in the same site, while the species in the outermost layer also desorb into the gas, as gas-phase species accrete onto the outermost monolayer. The choice of which process happens in which time period depends upon the approach utilized. In the continuous time random-walk approach, a kinetic Monte Carlo approach used most commonly in the astrochemical literature, a Poisson (or waiting time) distribution

($\psi_a(t) = k_a \exp(-k_a t)$) is used, where k_a is the rate coefficient for process a , and its inverse is the average time between events for process a . Distributions are used for four discrete and competitive types of events: hopping between adjacent sites, desorption, deposition (accretion), and reactions, which can occur diffusively by the Langmuir-Hinshelwood mechanism, or via a direct hit during deposition according to the Eley-Rideal mechanism. Diffusive reactions occur when two species hop or tunnel into the same lattice well, and the possible reaction does not have a very high activation energy barrier. For a significant barrier, the possibility of tunneling must be included. The waiting time WT for each event a is defined by the equation $WT_a = -\ln X/k_a$, where X is a random number in the range 0 to 1. Note that $X = 0.5$ corresponds to a waiting time of $0.693/k_a$. As each process gets a waiting time and the clock moves forward, the process with the nearest waiting time undergoes the next process and afterwards receives another waiting time. Meanwhile, the clock moves once again to the process with the shortest time before execution. As in the macroscopic case, the microscopic Monte Carlo approach must be run more than once.

At their current stage of development, microscopic Monte Carlo models of grain chemistry can now include hopping and reactions in the bulk of the ice mantle and can be coupled to macroscopic Monte Carlo models of the gas-phase chemistry. The combined gas-phase grain chemistry simulations are still limited to times shorter than the lifetimes of interstellar clouds and to temperatures not much higher than 20 K because of the greater expense of running them to longer times and at higher temperatures (Chang and Herbst 2016). There are intermediate models, which contain a degree of complexity in between the microscopic and macroscopic approaches. One such model has been used to model the chemistry that occurs as material near a protostar heats up (Vasyunin and Herbst 2013). Moreover, fixed grid models are being replaced by models in which the surface species move according to potentials such as the pairwise Lennard-Jones (6–12) function as well as more complex potentials. These models have also been used to simulate how ice mantles form on individual grains (Clement et al. 2018).

Definition

Microbial mats are benthic small-scale ecosystems that generally develop under environmental conditions that exclude fauna, often referred to as “extreme environments.” The biogeochemical cycles in microbial mats are usually largely closed, although small fluxes of elements are exchanged with the geo-, bio-, and atmosphere. An important feature of microbial mats is their

carbon and nitrogen autotrophy, i.e., the fixation of inorganic carbon and atmospheric nitrogen are key processes. In illuminated environments, therefore, the photoautotrophic cyanobacteria are the mat-building organisms while in the deep sea or in some caves, chemosynthetic bacteria and archaea are the primary producers.

Overview

The term *microbial mat* originates from the macroscopic structure that these small-scale microbial ecosystems often adopt. Large filamentous microorganisms grow and form an entangled mass with the sediment particles on which they grow, stabilizing the sediment surface and themselves from eroding forces. Mature microbial mats can sometimes be lifted in large pieces from the sediment, just like a doormat. However, in the course of the research on microbial mats, the term has been used for any benthic microbial community that forms a macroscopic structured entity. An important driver for the study of microbial mats is that these systems are considered to be analogues of the Precambrian stromatolites, which have been recognized as the oldest known ecosystems on Earth, and their study could lift the veil of the evolution of early life.

Microbial mats often develop in environments and habitats that are characterized by extreme conditions that exclude metazoans that would otherwise graze on the microbes, preventing

them from forming a microbial mat. Microbial mats are largely closed ecosystems. This means that the biogeochemical cycles are basically closed. Therefore, a basic characteristic of microbial mats is that they are carbon autotrophic, meaning that they grow by fixing inorganic carbon. This can be done in two principally different ways, namely, by photosynthesis and by chemosynthesis. In the former, light is the source of energy and phototrophic organisms are the organisms that build the microbial mats. In chemosynthetic microbial mats, the source of energy is the oxidation of a reduced compound, often sulfide or methane. In most illuminated environments, the phototrophic cyanobacteria are the mat-building organisms. In dark environments such as in the abyssal of the oceans or in caves, hyperthermal springs, mud volcanoes, and cold seeps provide reduced compounds produced by the Earth's internal heat that drive chemosynthesis. Chemosynthetic mats may also develop in illuminated environments when, for instance, the decomposition of large amounts of organic matter in seawater produces high amounts of sulfide which is in direct contact with oxygen.

Since Precambrian stromatolites are known to have developed in shallow, illuminated coastal environments, the study of coastal microbial mats deserves special attention. Microbial mats develop in coastal intertidal sandy sediments (Fig. 1). These environments can be considered as extreme because they are periodically inundated,

Microbial Mats, Fig. 1 (a) Microbial mats growing on a sandy intertidal beach. (b) Cross-section of this mat shows the typical varicolored layers with a *purple layer* of

anoxygenic phototrophic bacteria right underneath the layer of cyanobacteria

desiccated, hyper- or hyposaline, experiencing high and low temperatures, and as a rule nutrient poor. Cyanobacteria thrive well under such conditions. As photoautotrophs, they use light, water, and CO₂ as source of energy, electrons, and carbon, respectively, which are abundantly available. Many cyanobacteria are also nitrogen autotrophs, i.e., they can utilize atmospheric N₂, the most abundant form of nitrogen on Earth and after carbon the second most important element for life. Cyanobacteria have low nutrient requirements, possess high-affinity phosphate uptake systems, and contain a variety of storage compounds.

The carbon fixed by the cyanobacteria is made available to the microbial community by a variety of different ways. In the light, photorespiration may result in the excretion of glycolate while in the dark, the storage compound glycogen may be fermented to low-molecular compounds such as acetate, lactate, and ethanol. Cyanobacteria exude also exopolymeric substances and upon salinity down shock may release compatible solutes such as the carbohydrates trehalose and sucrose and the polyol glucosylglycerol. Finally, cyanobacteria may die and lyse, providing another source of organic matter and nutrients. A plethora of microorganisms will degrade these compounds, but the sulfate-reducing bacteria deserve a particular notice in marine microbial mats. At night, when oxygenic photosynthesis ceases or in the deeper aphotic layers of the mat, oxygen is quickly consumed by the microbial community, including the cyanobacteria. This happens often within minutes. Sulfate-reducing bacteria are therefore responsible for the bulk of the degradation of organic matter using the abundant sulfate (28 mM) in seawater as electron acceptor, reducing it to sulfide. The sulfide is subsequently oxidized in two ways. In the light, anoxygenic phototrophic purple sulfur bacteria use sulfide as the electron donor for photosynthesis. They oxidize it to elemental sulfur and eventually back to sulfate. These bacteria are basically anaerobic and form a pink layer below the cyanobacteria where they experience anaerobic conditions while sufficient light (particularly of the far red wavelengths) reaches them. The other group of microorganisms that oxidizes the sulfide is the colorless sulfur bacteria. They use oxygen or nitrate as electron acceptor.

As a result of the microbial activities, microbial mats are characterized by steep and fluctuating physicochemical gradients. Only during the day, oxygenic photosynthesis by the cyanobacteria enriches and supersaturates the sediment with oxygen. During the night, this oxygen is quickly respired. Sulfide accumulates during the night because light and oxygen (and usually nitrate as well) are lacking for its oxidation while the sulfate-reducing bacteria are continuing to produce it. During the day, sulfide is oxidized. The day-night rhythm and the activities of the mat microorganisms result in the continuously shifting gradients of oxygen and sulfide. Together with that, the pH shows dramatic shifts. During the day, the fixation and the consequent depletion of CO₂ causes the pH to rise to high levels (>9), while during the night, the decomposition of organic matter causes the level of CO₂ to increase and the pH to decrease (Fig. 2).

The mat-forming organisms take their positions in these physicochemical gradients. The aerobic cyanobacteria form a green layer at the surface while the anaerobic purple sulfur bacteria form a pink layer right below them. Often, a rusty layer separates them. This layer is supposedly composed of iron which forms a barrier for both oxygen and sulfide, which are toxic to the purple sulfur bacteria and cyanobacteria, respectively. Sulfide diffusing to the surface reacts with iron and oxidizes to elemental sulfur and forms insoluble iron sulfide and pyrite. Oxygen diffusing downward reacts with the iron and oxidizes it, forming iron hydroxides. It is also possible that anoxygenic photosynthetic iron-oxidizing bacteria thrive in this layer, but hitherto, this has not been demonstrated. Sulfate-reducing bacteria are obligate anaerobic microorganisms, although some can tolerate low levels of oxygen or are even capable of respiring it, although they are unable to live by aerobic respiration. For these reasons, it has been assumed that sulfate-reducing bacteria are mostly present in the permanent anoxic layers of the microbial mat. This is not the case. Sulfate-reducing bacteria occur throughout the microbial mat although the different groups show a distinct depth distribution, particularly with respect to their oxygen sensitivity. Microbial mats have also been termed laminated microbial ecosystems. The lamination is

Microbial Mats,

Fig. 2 Cartoon of a microbial mat indicating the vertically stratified and varicolored layers of functional groups of microorganisms and the chemical gradients they produce during the day (left) and during the night (right)

the result of the vertically stratified communities of different functional groups of phototrophic microorganisms, notably the cyanobacteria and the purple sulfur bacteria (and in some cases also green sulfur bacteria), giving the mat a varicolored appearance. This lamination is also called an instantaneous biological lamination to distinguish it from a historical lamination which is produced by successive microbial mats, while the older mats are only partly degraded (compare with the rings of a tree). This is often seen under extreme conditions such as hypersaline or hyperthermal environments. This historical lamination is also preserved when the mat turns to stone, i.e., when calcification takes place.

Stromatolites are by definition laminated rock and are known from the fossil record up to almost 3.5 billion years before present. The majority of modern microbial mats do not turn to stone, although it is uncertain whether this has always been like this. The fossil record also indicates the presence of noncalcified microbial mats through features known as *Microbial Induced Sediment Structures* (MISS). It is not fully clear why some mats calcify and others apparently do not. It is hypothesized that extracellular polymeric substances (EPS) produced by the *Cyanobacteria* bind calcium, thereby lowering the solubility product of calcium carbonate. When the EPS is degraded, calcium is locally released causing

saturation of calcite. Modern marine stromatolites are rare and found only in the Exuma Cays (Bahamas) and in Shark Bay (Western Australia). Stromatolites with remarkable similarity to those of the Precambrian are found in alkaline environments which may hint to an alkaline Archean ocean. It has been shown that calcification occurs in microbial mats that do not lithify, but the calcite in these mats dissolves as a result of microbial metabolism.

Definition

Microbially induced sedimentary structures (MISS) are structures caused by biofilms and

microbial mats in siliciclastic deposits. The microbenthos responds with biostabilization to erosion, gas pressure, or evaporite mineral crystallization. Biostabilization is the fixation of grains by biofabrics and mucilages. Deposition triggers baffling and trapping: microbial filaments orientate vertically and move upward with the sedimentation rate. During dynamic quiescence, called latency, binding and growth establishes a new biofilm or mat. MISS occur in modern aquatic settings, but are abundant since the early Archean. In microscopic close-up, MISS include biofilm or mat textures, in fossil examples *in situ* preserved.

Overview

Siliciclastic sediments in coastal zones as well as in lacustrine and fluvial settings are widely colonized by microbial mats. Microbial mats are coherent organic layers covering sometimes several km² wide areas. In a microbial mat, many microorganisms occur, although in the modern time, photoautotrophic cyanobacteria are the main mat constructors. The pigments of cyanobacteria give rise to a typical bluegreen or pink color of the mats. Benthic microorganisms including cyanobacteria secrete adhesive mucilages, called extracellular polymeric substances (EPS) (Decho and Gutierrez 2017). The slimy secretions serve a number of purposes such as attachment of the microbes to a hard substrate. Freshly deposited sediment is quickly populated by cyanobacteria. Initially, single grains are overgrown by thin biofilms that over time may develop to macroscopic microbial mats. Microbial mats tend to accumulate at sites of moderate hydraulic reworking, not strong enough to destroy the mat fabrics but still prohibiting fall-out of fines. Within a biofilm or microbial mat, the constituent microbial groups are spatially arranged in a fashion that allows interlocking of their metabolic activities and optimizing the harvest of light and nutrients (Visscher and Stolz 2005).

Because microbial mats colonize the sedimentary surface, they must respond to sediment-dynamics affecting their substrate. In carbonate settings commonly of the tropical climate zone, microbial mats may form stromatolites, whereas

in clastic settings, a mechanistically complex interaction of microbenthos with sediment dynamics causes MISS (Grey and Awramik 2020). The morphologies of MISS do not resemble stromatolites, and they differ also from that of abiotic sedimentary structures, for example, ripple marks.

While MISS are known from modern environments (Gerdes et al. 1985; Carmona et al. 2012; Taher 2014; Maisano et al. 2019; and many more), fossil MISS are abundant as well (Schieber 1989; contributions in volumes by Hagadorn et al. 1999; Schieber et al. 2007; Noffke and Chafetz 2012; and many more). MISS allow detailed conclusions on climatological conditions, modern and past (overview in Noffke 2010). Ecologically and taphonomically significant are fossil microbial mats in the Neoproterozoic Ediacaran world (Gehling and Droser 2009, and many more). MISS in early Archean rocks (Noffke et al. 2008, 2013; Heubeck 2009; Noffke 2010; Homann et al. 2015, and many more) serve as models for biosignatures for life detection on Mars. The 3.48 Ga Dresser Formation exposed in the North Pole Dome, Pilbara, West Australia, includes MISS and stromatolites witnessing a complex and very early microbial ecosystem in a coastal sabkha setting (Noffke et al. 2013).

Basic Methodology

Formation of MISS is studied in modern aquatic environments, commonly in long-term observation (Noffke 2010). Laboratory experiments allow a better understanding of specific microbial behavior (Bebout and Garcia-Pichel 1995; Shephard and Sumner 2010; Mariotti et al. 2014, and many more). The prospection for fossil MISS is guided by the paleoenvironment that must have provided suitable life conditions for microbenthos. Sandstone beds of less than 20 cm thicknesses with well-preserved surfaces chronicling an ancient environmental surface seem to be most promising for MISS detection, especially if composed of more than 90% quartz grains. Geological field work documented concentration of MISS at transgression-regression branches

(Noffke et al. 2002). The morphologies of MISS seem not to have changed over Earth history (Noffke et al. 2013), so the comparison of morphologies of fossil structures with modern ones assists in confirmation of biogenicity. More so, MISS rarely occur as single phenomena but form associations with respect to the geomorphology of the ancient environment (biofilm-catenae). In thin-section view, modern and fossil MISS-samples include a wealth of microbially induced sedimentary textures (MIST) that in concert with their biological isotope signatures confirm biogenicity of a structure under consideration (Noffke et al. 2021).

Key Research Findings

MISS form and preserve in all clastic depositional settings as long as water is accessible. Microbial mats and biofilms causing MISS develop during periods of time during which the sedimentary surface is undisturbed. The assembling of a biofilm by actively moving microbes is referred to as “binding.” Growth, in contrast, is the enrichment of biomass through cell replication and EPS production. With respect to thickness of the microbial mat and its location in relation to the sediment, epibenthic (=on the seafloor living) mats and endobenthic (=within the sedimentary surface living) mats are being distinguished. Thick microbial mats, commonly of epibenthic type, show oriented grains in thin sections (Fig. 1a). The grains appear to be floating without grain-grain contact in the mat fabrics. During growth of the mat, individual sand grains of the substrate were dragged upward by the adherent EPS-rich biomass. Often the long axes of the grains are oriented parallel to the overburden pressure. Epibenthic microbial mats, especially those in semi-arid climate zones, may display seasonal varves in vertical section. Such a mat is called biovarvite (Gerdes et al. 1985).

Sedimentary particles that fall out of slow-moving water currents may trigger a vertical orientation of cyanobacterial filaments on the mat surface. The filaments protrude into the supernatant water, where they foster deposition of silt-

sized sedimentary grains and heavy minerals. The behavior is known as baffling and trapping. Once buried, thin biofilm or endobenthic mats may line (imprint) the proceeding sedimentary surface. Was this surface rippled, their biofilm-drape now forms sinoidal structures visible in vertical section through the sediment.

What happens, if a microbial mat is affected by erosion? In microscopic close-up, the mat fabrics interweave the sand grains of the substrates and embeds them in ubiquitous EPS. This construction of a “network plus glue” (Fig. 1b) stabilizes the grains in their position, so they cannot be eroded anymore. By this biostabilization

(Paterson 1997), the erosive shear forces of horizontally directed water currents are reduced that otherwise may rip off pieces (=mm- to cm-sized mat chips, Fig. 2a) of microbial mat. Intra-sedimentary gases cannot escape through the EPS-rich microbial mat layer, causing local upheavals (mm- to dm- scale gas domes) or a high porosity (sponge pores, Fig. 2b) in the mat.

Shelf deposits commonly show wrinkle structures (Hagadorn and Bottjer 1997; Noffke 2000) and mat chips. This is different in shallow water facies. Here, erosional remnants and pockets (Fig. 2c), multidirected ripple marks (Fig. 2d), and mat chips are caused by water currents

Images (a–d) from Dakota Sandstone, Cretaceous, Colorado, USA. (e) Petees, Yalgorup Lake System, Australia; scale 10 cm; image by Alexander Brasier (f) Polygonal oscillation cracks, Abu Dubai tidal flats; scale 5 cm; image by Stephen Lokier

crossing the sedimentary surface. Gas domes may occur during episodes of subaerial exposure. Where evaporation in semi-arid and hot climate zones influence MISS-formation, petees (not: tepees!) and polygonal oscillation cracks develop (Fig. 2e, f). Both structures rise from vertical groundwater migration and periodic desiccation. In terrestrial settings such as interdune areas or flood plains, mat chips and roll-ups are frequent (Eriksson et al. 2000; see contributions on

terrestrial MISS in the volume by Noffke and Chafetz 2012).

In situ precipitation of carbonate minerals, fundamental for stromatolites, does rarely, if at all, take place in MISS-development (Grey and Awramik 2020). However, *in situ* mineralization of microbial mat fabrics by heterotrophic microbes is observed. In thin-section view, MISS include a wealth of various textures lined by pyrite and clay minerals and accompanied by biological

Microbially Induced Sedimentary Structures, Fig. 3 Classification diagrams of MISS (a) and MIST (b)

isotope signals. Organic carbon may still be present in very small amount, even in oldest specimen of Archean ages (Noffke et al. 2013). The microscopic view reveals filaments forming a microbial network, oriented grains, mat-layer bound small-sized grain populations, and microsequences (Fig. 1b, c). Heavy metal concentrations may trace a mat layer as well. MISS and MIST are classified in accordance to their formation (Fig. 3).

Exceptionally well preserved are MISS in the 2.8 Ga Nhlazatse Section (Pongola Supergroup) that crops out along the river Wit Mfolozi, South Africa (Noffke et al. 2008). The 46 m rock succession comprises MISS that change in morphology over time, recording a tidal flat that moved from a position in a moderate to a semi-arid paleoclimate zone. Indeed, the MISS show morphologies, associations, and distribution as known from modern coasts of the North Sea and the Mediterranean Sea. The same is to be said from the internal variation of MIST.

In the Nhlazatse Section, endobenthic microbial mats in the upper intertidal zone display multidirectional ripple marks recording seasonal storms. Mat chips cover rippled surfaces. Thin sections include microsequences that witness cyclicity of sediment dynamics.

Epibenthic microbial mats of the lower supratidal zone have been of three main types (spongy,

tufted, and planar). Spongy mat types were restricted to permanent tidal pools. Their internal construction is identical to that of modern mats in tidal pools of the Bahamas (Fig. 2b). Tufted mats grew in very shallow depressions periodically subaerially exposed. The fossil tufted microbial mats are arranged into polygonal oscillation cracks. In the modern, such cracks are only developing in settings dominated by a semi-arid, hot climate. During the dry season, the microbial mats crack due to desiccation, and mat-polygons form. The margins of the mat-polygons may curl up due to desiccation of the mat. During subsequent seasons of high humidity and/or shallow flooding of the microbial mats, the mat-polygons expand laterally and close the former cracks. The curled-up margins are now overgrown by a new generation of microbial mat. Repetition of this process results in the characteristic polygonal oscillation crack pattern. Due to the thick bulges that mark the former margins of the mat polygons, the former cracks are lined by two parallel running ridges.

The planar mat type at the Pongola site grew in elevated areas between tidal channels that were flooded only episodically. Such microbial mats gave rise to erosional remnants and pockets (Fig. 2c) and gas domes. Erosional remnants and pockets form from partial erosion of a microbial mat. Gas domes witness gas production through metabolic activity as well as mat decay. In the

outcrop, mat chips were produced by both epibenthic and endobenthic microbial mats.

Applications

The significance of MISS lies in the information they provide with respect to paleoenvironments including paleoclimate conditions, the decoding of the evolution of early life, as well as the exploration of other terrestrial planets. Regarding missions to clastic-rich Mars with remotely controlled rovers, the wide variety of MISS on Earth and their vast abundance qualifies them as potentially important biosignatures. That said, martian MISS likely would be of small scale and not include meter-sized structures such as erosional remnants and pockets.

Future Directions

The overall group of MISS is well known by now; however, the many facets of application are still harboring opportunity for further exploration. Given the many clastic deposits on Mars, future missions to Mars will scout for MISS in clastic deposits of ages equivalent to the Archean time on Earth.

Microorganisms on board the International Space Station

Definition

A microbiome is defined as the combined genetic material of microorganisms in a particular environment, here the indoor environment of the International Space Station. It includes information about the identity of the microorganisms as well as their functional abilities.

Overview

Since October 30, 2000, the International Space Station (ISS) has been constantly inhabited by humans and accompanying microorganisms and represents a unique but challenging indoor environment in Earth orbit.

The ISS composes one of the most confined man-made and inhabited environments and

harbors a number of specific physical and chemical parameters: higher radiation levels than on Earth, low nutrient levels due to regular cleaning and reduced introduction of new material, constant temperature (approx. 22 °C), humidity of 36–80%, and microgravity characterize the ISS habitat.

Investigating the ISS microbiome is of utter importance to guarantee safety of the crew and the spacecraft itself, and microbial monitoring is pursued by all involved space agencies (Wilson 2019). The ISS also serves as a testbed for long-term space missions, and insights into microbial dynamics support preparation for such missions.

Crew members are the only constant source of microorganisms onboard the ISS; the input of microorganisms through cargo or other sources is minor. As a result thereof, the composition of the ISS microbiome is very similar to that of a typical human and ground-based indoor environment microbiome, which has been shown by all studies investigating the ISS microbiome so far.

However, within these bounds, the ISS microbiome shows adaptations toward the localization within the ISS, although diversity is fluctuating over time, even over a timespan of 2.5 months (Mora et al. 2019). Metagenomic analyses have shown that these fluctuations also seem to lead to an increase of antimicrobial resistance and virulence genes over time (Singh et al. 2018; Urbaniak et al. 2018).

However, up to date, no health-threatening differences have been found when comparing isolates and/or metagenomic data from the ISS with closely related isolates or metagenomic data from comparable indoor environments or the human microbiome on Earth (Blaustein et al. 2019; Mora et al. 2019). This is also supported by the fact that only a relatively low number of health issues related to pathogenic action of microorganisms onboard the ISS were reported (Crucian et al. 2016).

Nevertheless, studies also show that the ISS environment – while not inducing changes in microbes on a genomic level – seems to select for hardy microorganisms which are specialized to survive under these special environmental conditions. This microbial specialization to spacecraft

environment can also be seen when investigating the interaction of ISS isolates with spacecraft relevant material (SRM). Microbial isolates from ISS have been shown to be able to adhere to different kinds of SRM and to form a biofilm on such material (Mora et al. 2019), and other microbial isolates from ISS, so-called technophilic microorganisms, have also been shown to be able to damage SRM (Alekhova et al. 2005; Wilson 2019). These technophilic microorganisms had become a major problem on the Russian space station MIR (Novikova 2004).

Information on the ISS microbiome is critical to assess the microbial risk of long-term space missions. However, such flight bears even more extreme environmental factors, with complete isolation from the terrestrial biosphere, and it cannot be predicted how the microbiome therein would develop and whether elevated risks for crew and spacecraft material would occur.

Morphological fossils

Definition

A microfossil is a microscopic morphological remain of an organism. It may represent a whole or part of a microscopic or macroscopic organism.

The organism may be a unicellular or multicellular prokaryotic or eukaryotic organism, or a virus.

Overview

Microfossils can have a variety of morphologies and chemical compositions, depending on their original properties and the conditions in which they are preserved. Microfossils can have a carbonaceous composition or a mineral composition. The mineral composition can be primary (produced or precipitated by the organism) or secondary (the original carbonaceous or mineral walls or envelopes being in that case partially or completely replaced by other minerals).

Microfossils are studied by micropaleontologists and provide useful information on the evolution of the biosphere, for biostratigraphy (dating sedimentary rocks), and for paleoecology, through most of geological time.

Possible microfossils have simpler morphologies and smaller size as we look further back in time through the early Earth rock record. Moreover, abiotic processes can produce structures resembling microfossils (► **Pseudofossil**). Deciphering the ► **biogenicity** of an object is very difficult even using cutting-edge in situ techniques. Several criteria have been proposed in the literature to test the biogenicity of microstructures preserved three-dimensionally in cherts or silicified carbonates or phosphorites, or flattened in two dimensions in fine-grained siliciclastic rocks. Most criteria underline the importance of a well-characterized geological context as the environmental conditions will determine the conditions of fossilization.

Three criteria need to be reached in order to correctly interpret a particular structure as a microfossil: (1) ► **endogenicity**: the microstructure is within the rock and not a contaminant; (2) syngeneity: the microstructure has the same age as the rock and is not a younger fossilized contaminant such as an organism boring the rock or transported by fluids between pores or veins through the rock; (3) biogenicity: the microstructure has a biological origin. Not only must

biogenicity be demonstrated, but all possible abiotic hypotheses must be excluded before a biological origin can be accepted. Several analytical techniques coupled to observations of the microfossil in situ in sections cut through the rock are used to prove the points above.

Geobiological studies in recent and past environments and laboratory experiments can improve understanding of preservational environments and fossilization processes, and help to recognize morphological (and other) traces of life on early Earth and beyond Earth. This is essential to choose landing sites, instrumentation, and samples to return in exobiological missions.

Definition

Versatile analytical techniques can provide morphological, structural, chemical, and mineralogical (bio)signatures for microscopic fossils. These signatures can be used to distinguish microfossils from pseudofossils, demonstrate their antiquity, identify their parent (micro)organisms (taxonomy), and decipher their activities and host environments. Most of these techniques rely on electromagnetic (X-ray, UV, visible, IR) radiation or particle (electron, ion) beams. They can produce images in two and three dimensions, perform spectroscopy and spectrometry in situ down to the nanometric scale, and generate maps of specific chemical, structural, or crystallographic features.

Overview

Morphological analysis of microfossils can be performed in three dimensions with the following techniques (in order of spatial resolution, from $\sim 1 \mu\text{m}$ to 10's of nm): multiplane transmitted-light microscopy, Raman spectromicroscopy, CLSM, FIB-SEM, and S-XRCT. Nanometric resolution of organic ultrastructures and (bio)minerals can be achieved in 2D at the surface of fossils with SEM and in their cross-sections with TEM. These morphological analyses can help distinguish microfossils from pseudofossils and assess the preservation and taxonomy of microfossils.

Elemental compositions of minerals and organic matter can be analyzed in 2D with EDX, SIMS, and ToF-SIMS, as well as in 3D using S-XRF. This helps further assess biogenicity and conditions of fossilization. Crystallographic characterization can be performed with EBSD and TEM, which can document on fossilization, biomineral formation, and pseudofossil generation processes.

The thermal evolution of carbonaceous matter, in rocks that are sufficiently mature, can be quantified with Raman spectroscopy, thus providing constraints on syngenicity. Organic functional group signatures shown by FT-IR and XANES spectroscopy, and molecular formula obtained by mass spectrometry (Py-GCMS, ToF-SIMS) demonstrate selective preservation of specific types of biomacromolecules in distinct (micro)fossils. Chemotaxonomic constraints and biogenicity indices may thus be derived. Measurements of the isotope ratios (e.g., of C, N, O, and S) can be performed at the microscopic scale with SIMS. These can be used to infer metabolisms and/or conditions of fossilization.

The association of these techniques has proven crucial for investigating microfossils. It can be facilitated by spatially correlative microscopy and microanalyses, currently developed for many of the techniques mentioned herein. An analytical sequence is developed here that copes with the destructive nature of some analyses and some types of sample preparation.

Basic Methodology

Preparation

Microfossils can be analyzed in 30–100 μm -thick polished “petrographic” sections preserving their mineral matrix. Nanoscale focused ion beam (FIB) abrasion allows extraction of ultrathin (usually ~ 100 nm thick, <30 μm wide, <12 μm deep) sections cross-cutting organic fossils and host minerals that can be analyzed at the nanoscale in transmission electron microscopes (TEM) (Brasier et al. 2015; Lepot et al. 2017). Demineralization of organic microfossils (using acid maceration in HCl, acetic acid, HF, and/or HNO_3) allows their analysis without matrix interference and reveals microfossils compacted by sedimentation (Javaux et al. 2004). HNO_3 alters immature-to-mature fossil organic matter, and HCl alters “fresh” biomass (Lepot et al. 2014). Demineralized microfossils can be embedded in glycerol or resins to prepare “palynological” slides. Furthermore, demineralized fossils can be analyzed at the nanoscale when included in polymers and cut using an ultramicrotome into ultrathin (~ 100 nm) sections for TEM (Javaux et al. 2004). Ultrathin samples are also required for transmission of low-energy “soft” X-rays used to analyze light elements (C, N, O, S) with XANES: they can be prepared with FIB (Bernard et al. 2007). Higher energy X-rays such as those used to study trace metal abundances (see S-XRF) can transmit through unglued petrographic sections. For transmitted infrared spectroscopy, best-suited are mineral samples that are at most tens of micrometers in thickness and demineralized organic microfossils. Fluorescence spectromicroscopy techniques operate with petrographic sections or demineralized microfossils, although care should be taken to avoid fluorescent embedding media (Lepot et al. 2014). Raman spectromicroscopy operates on any sample type and can target fossils encapsulated in transparent minerals, hence limiting superficial laser-irradiation damage and preparation artifacts.

Transmitted Light Microscopy

Transmitted, visible light microscopy allows 3D observation of microstructures. The diffraction

limit on a microscope lateral resolution follows Abbe’s law ($d = \lambda/2\text{NA}$, with λ : wavelength, NA: numerical aperture of the objective). The average lateral resolution is thus ~ 300 nm with a standard objective (NA0.9), and ~ 200 nm with an oil-immersion objective (NA1.4). White light is usually the main light source used, and infrared can also be used to transmit through some opaque phases such as FeS_2 , which is a common postmortem replacement/mineralization of organic anatomy (Wacey et al. 2013; Lepot et al. 2017). The in-focus slice thickness is also proportional to the numerical aperture of the objective used (e.g., >0.6 μm with a 100x NA0.9 objective, >5.6 μm at 10x NA0.3). Additionally, deformation along the optical axis (vertical direction) occurs when the refractive indices of the microfossil matrix (mineral, mounting medium) and those of the media between sample and objective (air, or water, or immersion oil, and/or coverslip) differ. This, combined with the large contribution to the transmitted-light intensity of dark out-of-focus objects, limits the spatial resolution along the optical axis. Stacks of images recorded at different focal depths can be used to render 2D projections of microfossils preserved in 3D by subtracting the low-contrast contributions of out-of-focus parts of the images and combining the remaining contrasted zones (Fig. 1a and b). Similarly, combination of multifocal image stacks acquired using reflected light can help reconstruct images of the topography of thick and/or opaque samples such as (micro)fossils on fracture surfaces. Analyzed polarized transmitted light can reveal mineral microstructures, help identify minerals, and distinguish their respective orientations. Thermally mature organic matter can be tracked over surfaces using reflected light, and quantification of the reflected light intensity can help assess maturity.

Fluorescence (Spectro)microscopy and Confocal Laser-Scanning Microscopy

Fluorescence emission is generated by excitation of electrons by incident photons, followed by non-radiative relaxation (e.g., heat-generating) and radiative relaxation of the excess energy in form of photons of lower energies than that of the

Microfossils, Analytical Techniques, Fig. 1 White-light microscopy and CLSM of a ~407 million-year-old microfossil from the Rhynie chert of Scotland. (a) Single plane photomicrograph. (b) Multiple image resulting of the combination of multiple single focal-plane images. (c) 3D rendering of CLSM image stack. (d) single plane CLSM image and (e, f) orthogonal depth slices extracted along the green and red lines in (d). Blue lines in (e, f) mark the depth

of the single plane slice shown in (d). Sample provided by N. Trewin (U. Aberdeen). CLSM performed by E. Richard (Univ. Lille, CNRS, INSERM, CHU Lille, Institut Pasteur de Lille, US 41 - UMS 2014 - PLBS, F-59000 Lille, France), using 40x NA1.3 objective, color channels (laser excitation, light-collection range): blue (405 nm, 410–513 nm), green (488 nm, 490–606 nm), and red (561 nm, 570–641)

M

incident photons. Fluorescence can arise from in situ autofluorescent molecules such as chlorophylls and carotenoids, minerals (e.g., carbonates), fossil organic matter (Schopf and Kudryavtsev 2010; Lepot et al. 2014), or chemical dyes that can be added to bind to selective classes of molecules such as nucleic acids, proteins, or polysaccharides. Filters allows the selection of specific excitation and emission wavelengths to image distinct components. Fluorescence in situ hybridization (FISH) uses fluorescent probe molecules that can be designed to bind to specific nucleic acid sequences, which allows identification of cells at the gene level, and to visualize the expression of certain genes (e.g., those linked with a specific metabolism). Epifluorescence microscopes share the lateral/vertical resolution limits of white-light microscopy, albeit at increased lateral resolution using UV excitation, following Abbe's equation. Confocal laser-scanning microscopes (CLSM) provide increased resolutions in 3D using lasers of various wavelengths to induce specific fluorescence emissions.

A focused laser beam is raster-scanned on the sample and out-of-focus fluorescence emission is removed by a pinhole. This produces confocal images with a focalized slice thinner than 0.5 μm , and with a lateral resolution of ~200 nm or better. Depth series of 2D images can be combined to reconstruct 3D projections and orient virtual slices in any direction (Fig. 1c–f; Schopf and Kudryavtsev 2010). CLSM can acquire hyperspectral stacks of fluorescence maps over a range of wavelengths, from which fluorescence spectra can be extracted in specific regions of interest that may indicate the origin of autofluorescence (Lepot et al. 2014).

Raman Spectromicroscopy

Raman spectroscopy uses monochromatic beams of photons (from X-ray to near-infrared wavelengths) to excite molecules to virtual energy states. The molecules then relax to various final energy states (e.g., vibrational, see next section). In doing so, they backscatter photons with energies equating that of the absorbed photons minus

the various energy differences between initial and final states of the molecules. The differences between the energy of the incident laser and the energies of the backscattered photons are named Raman shifts, expressed in wavenumbers (cm^{-1}). They are mostly independent of the incident wavelength, and are measured as bands with spectrometers. Minerals and organic molecules generally produce spectra with multiple characteristic bands. Minerals (and their polymorphs) and plastics are readily identified by automated comparison of Raman spectra with databases. Various functional groups (e.g., C=O, O–H) can be distinguished in living/fresh organic matter, and

some biomolecules such as pigments, which can survive for thousands of years in sediments, display intense Raman spectra with characteristic fingerprints (Lepot et al. 2014). Fluorescence emission may generate large humps in Raman spectra in some organic and/or inorganic materials. Immature fossil organic matter and carbonates can be highly fluorescent, and functional groups are best detected in immature fossil organic matter using near-IR excitation (Olcott Marshall and Marshall 2015). Mature fossil organic matter mainly yields broad and intense bands (Fig. 2a), the shape of which reflects the structure of the macromolecular aromatic network

Microfossils, Analytical Techniques,

((b–c) Reprinted from Earth and Planetary Science Letters, 312, Kevin Lepot, Karim Benzerara, Pascal Philippot, Biogenic versus metamorphic origins of diverse microtubes in 2.7 Gyr old volcanic ashes: Multi-scale investigations, 37–47, Copyright (2011), with permission from Elsevier)

(Henry et al. 2019). Although these bands may not bear diagnostic fingerprints of molecular groups, they can be used to assess the maturity of the fossil organic matter through deconvolution of the band profiles (Fig. 2a; Henry et al. 2019). Using automated sample displacement or raster-scanning of the laser position, hyperspectral mappings can be acquired in Raman spectromicroscopes in 2D (Fig. 2b and c) or 3D (Schopf and Kudryavtsev 2010) with resolutions of ca. 300 nm. Similar to CLSM, the high resolution in depth is achieved by use of a focused laser and sorting of backscattered beams by a pinhole. Due to its intense resonant signal, thermally mature fossil organic matter is easily mapped in most transparent mineral matrices.

FT-IR Spectromicroscopy

Infrared photons of specific wavelengths can be absorbed by a given chemical bond type, raising the energy of such bonds to vibrational states. Similar to Raman spectroscopy, Fourier-transform infrared (FT-IR) spectroscopy thus allows identification and semi-quantification (band area ratios) of types of chemical bonds in minerals and organics. Microfossils have been analyzed in the mid-infrared domain ($500\text{--}4000\text{ cm}^{-1}$, that corresponds to wavelengths of $20\text{--}2.5\text{ }\mu\text{m}$), as shown in Fig. 3. Mid-infrared absorption bands of minerals overlap those of many organic functional groups, which can be overcome by complete demineralization

Microfossils, Analytical Techniques, Fig. 3 FT-IR spectra of Silurian microfossils. Upper spectrum recorded on a chitinozoan, lower spectrum on an acritarch. Note the square drawn by IR-opaque windows used to select the analyzed area of the acritarch specimen. The chitinozoan is enriched in aromatic functional groups ($C_{\text{aro}} = C_{\text{aro}}$ and $C_{\text{aro-H}}$) and displays little, short aliphatic chains

(characterized by the abundance of CH_3 relative to CH_2 groups). The acritarch is dominated by CH_2 groups, indicating relatively longer aliphatic chains, and carboxyls ($\text{C}=\text{O}$). Microfossils provided by T. Vandenbroucke (U. Ghent), analysis carried by I. De Waele (LASIR, U. Lille)

of organic microfossils (Olcott Marshall and Marshall 2015). In contrast with Raman spectroscopy, functional groups can be distinguished in FT-IR spectroscopy of organic matter up to the anthracite maturity rank, and can be used to assess the origin and thermal maturity of the organics using semi-quantification of functional groups (Chen et al. 2015). Metamorphosed organic matter usually displays little infrared absorption bands. Spectromicroscopy can be performed on plurimicrometric targets in three main modes in standard micro-FT-IR instruments (Chen et al. 2015). First, infrareds condensed through a reflective objective onto the sample and transmitted toward a second objective can be analyzed on the spectrometer. Depending on their compositions, the thickness of microfossils should not exceed a few micrometers. Analysis using transmitted FT-IR of organic microfossils embedded in a transparent mineral matrix can be performed in unglued petrographic sections $\sim 40\text{ }\mu\text{m}$ thick, but is limited to the bands of organic functional groups absorbing in the $2000\text{--}3000\text{ cm}^{-1}$ domain, which are little affected by host minerals (Chen et al. 2015 and references therein). Second, reflected infrareds can also be analyzed, although reflectance spectra display differences in shape and intensity with transmittance spectra. Third, the attenuated total reflectance (ATR) technique uses a crystal put in direct contact with samples, probing a thickness of a few hundred nanometers to a few micrometers. In all three techniques, analyses can be carried on single spots. The spot size obtained with a 36x NA0.5 objective is ca. $60\text{ }\mu\text{m}$ large. The analyzed area can be reduced down to $\sim 5\text{ }\mu\text{m}$ using adjustable IR-opaque windows (Fig. 3) forming a “pinhole” above the collecting objective, but at the expense of spectral quality. Hyperspectral mappings can be performed for all three techniques where FT-IR spectra are recorded simultaneously at each pixel of a detector. The lateral resolution of micro-FT-IR imaging is limited by diffraction to 1λ (36x NA0.5 objective), that is $2.5\text{--}20\text{ }\mu\text{m}$ in the mid-infrared. Additional optics may enable $\sim 1\text{ }\mu\text{m}$ resolution. Synchrotron infrared sources also help increasing the resolution to a few micrometers with spatial filtering and multibeam techniques.

Finally, infrared spectroscopy coupled to atomic force microscopy (AFM-IR), whereby the nanoscale displacement of an ultrasharp tip by the thermal expansion generated through IR absorption by the sample is measured, which allows spatial resolution $<20\text{ nm}$ (Dazzi and Prater 2017).

Scanning Electron Microscopy

Scanning electron microscopy (SEM) scans a thin primary beam of electrons over the surface of a sample. The interactions between primary electrons and materials generate electrons (backscattered, secondary and Auger electrons) and photons (X-ray, cathodoluminescence) that can be analysed with specific detectors. Secondary electrons generate images that are strongly influenced by sample topography. Backscattered electron intensity is proportional to the average atomic number of the material, producing images with contrast linked to chemical heterogeneity. The spatial resolution of secondary and backscattered electron imaging can reach $\sim 1\text{ nm}$. Cellular components and textures (ultrastructures) of organic and mineral microfossils can be imaged both in cross-sections (Fig. 4) or at the surface of microfossils (Javaux et al. 2004; Cohen et al. 2017; Wacey et al. 2017). Electron backscatter

Microfossils, Analytical Techniques,
Fig. 4 Ultrastructures in SEM BSE image (polished section) of a *young* fossil unicellular eukaryote buried under 126 cm of sediments, Antarctic lake O-Ike. Most of the chemical contrast in this image arises from differential fixation of uranium (white layer) and osmium (shades of gray) to the different ultrastructures of the microorganism after heavy-metal staining preparation. Light gray to white angular particles are minerals

diffraction (EBSD) can be used to identify mineral crystallographic systems (hence distinguishing CaCO_3 polymorphs such as calcite and aragonite), to evidence the boundaries of crystal/grains of similar chemistry in petrographic sections, and to determine and map crystallographic orientations, e.g., in biominerals (Cusack 2016). Although SEM characterizes surfaces, it can be coupled to a FIB that ablates ultrathin superficial layers of materials. Sequences of FIB ablations and SEM imaging (and/or SEM-EDX, see below, and/or EBSD mapping) can be used to record image stacks in order to reconstruct 3D images of microfossils (Brasier et al. 2015; Wacey et al. 2017). FIB-SEM can also document targeted cross-sections of microfossils (Wacey et al. 2017), which can be more pristine than the surface of mechanically polished sections (Fig. 5, arrows).

Transmission Electron Microscopy

Transmission electron microscopy (TEM) can image ultrastructures with true nanometric resolution in ultrathin (<100 nm) samples. Illuminating samples with a beam of parallel electrons generates images displaying contrasts related to crystallographic orientation, crystal defects, chemical composition, and sample thickness. Selected area electron diffraction (SAED) of parallel electron beams can be used to identify crystal systems in regions larger than ~ 50 nm (Lepot et al. 2017). High-resolution TEM (HR-TEM) can image atomic structures with a resolution down to 0.07 nm, for example, to identify nanocrystals in (bio)minerals (Lepot 2020) or to assess the stacking of polyaromatic structures during metamorphism (Bernard et al. 2007). Electron beams can be focused to less than 0.1 nm and scanned over the samples in a fashion similar to SEM,

Microfossils, Analytical Techniques, Fig. 5 Analytical TEM, microfossil of the 1.88 Ga Gunflint microbiota. (a) Photomicrograph. hence providing scanning-TEM (STEM) images (Lepot et al. 2017). Bright-field and dark-field STEM imaging (Fig. 5a) displays contrasts generated by sample thickness, chemical composition, and crystal structure/orientation (diffraction contrast), whereas high-angle annular dark field (HAADF) STEM shows mainly chemical and thickness contrasts. Nanodiffraction mapping can be performed by scanning a focused transmitted electron beam over the sample surface, which provides crystallographic data in a fashion similar to EBSD, but with nanometric resolution. Finally, electron energy-loss spectroscopy (EELS) can be used in STEM to measure atomic compositions, to distinguish chemical bonding types and oxidation states, and to map such chemical speciation down to the sub-nm scale (Lepot et al. 2017).

Elemental Compositions with EDX

Upon electron impact, X-rays are produced from a superficial zone $\sim 0.2\text{--}1\text{ }\mu\text{m}$ large and deep in SEM, and $< 20\text{ nm}$ large in STEM for samples $< 100\text{ nm}$ -thick. Elemental compositions can be measured by energy-dispersive X-ray (EDX) spectroscopy with a sensitivity $> 0.1\%$ and a precision of $2\text{--}30\%$. Light elements such as C, O, and N are very difficult to quantify in organic matter. EDX can be used to map distributions of chemical elements (Fig. 5). The spatial resolution of EDX is limited by the generation zones discussed above.

Dynamic SIMS

Dynamic secondary ion mass spectrometry (SIMS) uses primary, focused beams of ions (e.g., Cs^+ or O^-) to sputter materials from multiple atomic/ionic/molecular layers at the surface of samples. Sputtered secondary ions are then separated by mass, and each mass window is counted using individual detectors. This allows the measurement of isotope ratios with sub-permil precision and of major to trace element compositions (Orphan and House 2009). Analyzed (that is, sputtered) pits are 50 nm to $\sim 40\text{ }\mu\text{m}$ large and a few nanometers to several micrometers in depth. Variable bias named “instrumental mass fractionations” arise in SIMS that depend on the geometry of the instrument (ion path), its tuning, the age of the detectors, and sample topography. Variations

in chemical compositions of the matrix (e.g., C_xH_y) hosting the analytes (e.g., ^{13}C and ^{12}C) may generate additional bias (Orphan and House 2009; Williford et al. 2013). Instrumental and matrix-induced biases have to be evaluated through repeated analysis of standard materials. Quantitative (or semi-quantitative) mapping of isotope ratios or chemical elements can be performed by raster-scanning the primary ion beam over the sample surface with a spatial resolution down to $\sim 50\text{ nm}$ (Orphan and House 2009).

Time-of-Flight SIMS

In time-of-flight SIMS (ToF-SIMS), ions are sputtered in vacuum by a primary focused ion beam during a short-timed pulse (Thiel and Sjövall 2015). The sputtered ions are accelerated in an electrical field, after which they travel in a time-of-flight tube at velocities proportional to their mass/charge ratios, that are in turn quantified by the time of arrival of the ions on the terminal detector. Hence, full mass spectra can be recorded from 0 to 1000+ atomic mass units (Thiel and Sjövall 2015). In contrast to dynamic SIMS, ToF-SIMS instruments usually operate in static conditions defined by relatively low primary ion dose densities (10^{12} to 10^{13} ions. cm^{-2}). This, together with the use of primary beams of clustered atoms (e.g., Bi_3^+ , C_{60}^+ , Au_n^+ , Ar_{2500}) that deposit their energy at much shallower levels than monoatomic sources (e.g., Ga^+ , Cs^+ , Ar^+) allows the release of high molecular-weight ions from the extreme surface (monolayer to $< 10\text{ nm}$) of samples (Thiel and Sjövall 2015). Lateral resolution down to $\sim 100\text{ nm}$ can be obtained, and high-resolution maps of organic and inorganic ions are acquired by raster-scanning the primary ion beam. Depth profiles can be obtained in 3D by progressive ion-sputtering of layers from the sample surface in a fashion similar to FIB-SEM. ToF-SIMS has been used to analyze various classes of biomarkers and biopolymers in environmental samples, fossils and sedimentary rocks, to analyze oily fluid inclusions or extraterrestrial organic matter (Thiel and Sjövall 2015). An important difficulty in ToF-SIMS arises from relatively large inaccuracy on measured masses (and lower mass resolution) caused by sample

topography (Thiel and Sjövall 2015). Polishing can level topography but specific methods are required to avoid or minimize contaminants (Fadel et al. 2020). With a mass resolution of 2,000–10,000 $m/\Delta m$, ToF-SIMS may not distinguish molecules of medium-to-high molecular weight in complex mixtures where multiple fragmentation patterns overlap, which may be overcome by additional tandem mass spectrometry available on some instruments (Thiel and Sjövall 2015).

Pyrolysis GC-MS

Gas-chromatography mass-spectrometry (GC-MS) provides an additional mode of molecule separation using a chromatographic column prior to analysis by mass spectrometry. This technique, compared with ToF-SIMS, requires large sample volumes to extract soluble molecules. The latter can also be analyzed by thermal desorption, and higher (pyrolytic) temperatures can fragment the insoluble macromolecular fraction (kerogen) associated with microfossils. Pyrolysis GC-MS has been enabled by handpicking of a few hundred similar microfossils (Dutta et al. 2007) or by laser-pyrolysis of one (large) to several microfossils (da Silva et al. 2016).

X-ray Nanotomography

X-ray computed tomography (XRCT) enables nondestructive 3D imaging even in thick and opaque matrices that could limit 3D CLSM imaging (Wacey et al. 2017). Microfossil analysis requires sub-micrometric resolution. Synchrotron-based instruments (S-XRCT) can achieve ~200 nm spatial resolution (Little et al. 2021). Ptychographic X-ray computed tomography (PIXCT) computes diffraction patterns generated using synchrotron X-rays to achieve ~50 nm resolution in 3D together with electron density estimates (Maldanis et al. 2020).

Synchrotron X-ray Fluorescence

X-ray fluorescence produced by synchrotron X-rays (S-XRF) allows mapping and quantification of the abundances of elements larger than sodium with ppm sensitivity and lateral resolution down to ~30 nm (Lemelle et al. 2020).

XANES Spectromicroscopy

Absorption of X-rays can delocalize inner-shell electrons to weakly bound states such as molecular orbitals. This generates absorption spectra with step-like (edge) increases displaying one, or multiple bands that are characteristic of the chemical bond types, the crystallographic environments, and the redox states of the elements. These spectral features are studied by X-ray absorption near-edge structure (XANES) spectroscopy (Bernard et al. 2007; Lepot et al. 2017) which can be performed in scanning transmission X-ray microscopes (STXM) and in scanning X-ray microscopes (SXM, also used for S-XRF, see above). STXM reaches ~25 nm spatial resolution but requires ultrathin samples, and SXM can reach <500 nm resolutions. In contrast with electrons used in EELS (see TEM), X-rays produce much less irradiation damage to sensitive minerals and organics.

Key Research Findings

Biom mineralization

Biom mineralization (or bioprecipitation) can be induced by the presence of reactive surfaces on (or secreted by) microorganisms, be induced by their metabolic activity, or result from genetically controlled processes. Most of the techniques described above have contributed to the understanding of biom mineralization. The association of multiple methods is necessary to clearly distinguish the signals generated by minerals and those by cells and/or organic molecules. At the ~0.1–1 μm scale, fluorescence spectromicroscopy can be efficiently associated with SEM and Raman spectromicroscopy in modern (Lepot et al. 2014) and fossil (Schopf and Kudryavtsev 2010) biom mineral-forming systems. At the same scale, ToF-SIMS can locate molecular biomarkers in association with single biom mineralized microorganisms (Thiel and Sjövall 2015). The coupling of synchrotron-based techniques and analytical TEM provide insight into biom mineralization at the nanometer scale.

The oldest record of controlled biom mineralization consists of phosphatic scales ~810 million

years old that have been attributed to unicellular eukaryotes (Cohen et al. 2017). In these scales, HR-TEM showed interwoven nanofibers that are elongated along a preferential direction, a crystallographic feature that is confirmed with SAED (Cohen et al. 2017). In this study, EDX spectroscopy demonstrated that the phosphate is a primary hydroxyapatite and abundant F and Cl substitutions indicative of diagenetic recrystallization were not detected. In older rocks, microbial calcification in 2.72 Ga stromatolites has been inferred by analysis of nanocrystalline CaCO_3 nanospheres using HR-TEM and XANES of associated organic matter (Lepot 2020).

Fe-mineralizations have been documented in close association with microfossils of the Paleoproterozoic. In a 1.74 Ga Fe-oxide-silica deposits, branching filaments were imaged in 3D with S-XRCT and STEM showed their tubular structures with walls of Fe-oxide nanoparticles (Little et al. 2021). These are interpreted as (recrystallized) products of Fe-oxidizing bacteria (Little et al. 2021). STEM showed that specific microfossil morphospecies in 1.88 Ga stromatolites display intracellular concentrations of nano- Fe^{2+} -minerals (Fig. 5). These were identified using a combination of EDX, nanodiffraction, EELS (that distinguished crystallographic environment of Si and the redox of associated Fe), and XANES (identifying CO_3^{2-} groups in Fe-carbonates) (Lepot et al. 2017). These Fe-minerals, in conjunction with the anatomy of the microfossils, were interpreted as the products of intracellular Fe^{3+} -mineralization by oxygenic phototrophs that have suffered postmortem reductive transformation (Lepot et al. 2017). Postmortem mineralization of organic ultrastructures of microfossils by Fe^{2+} -sulfides (Wacey et al. 2013; Lepot et al. 2017) and Fe^{2+} -carbonates (Fadel et al. 2017) was studied with STEM. Additional SIMS of S-isotope ratios supported an implication of heterotrophic sulfate-reducing microorganisms in the formation of the Fe-sulfides and the degradation of the associated microfossils (Wacey et al. 2013). In the Fe^{2+} -carbonate mineralization example, Fe-isotope ratios indicated a formation through reduction of Fe^{3+} -minerals, which may have been biomineralized initially by the

microorganisms represented by the observed fossils (Fadel et al. 2017).

Syngenicity of Organic Matter in Microfossils

Combined in situ characterization techniques have been used to seek textural relationships that demonstrate syngenicity, that is: a contemporaneous origin of microfossils with the earliest fabrics of the encapsulating rock. To this end, mapping of carbonaceous matter and associated minerals with Raman spectromicroscopy (Fig. 2) is useful. Contamination of the rocks postdating the most intense metamorphic (or deepest burial) history of the rock can be assessed variously. The color of organic matter evolves from near-transparent (fresh) to yellow (immature), to orange/brown (mature), and to black (metamorphic). Although colors may vary among taxa within a microfossil assemblage due to distinct molecular compositions and/or thicknesses (Fig. 3), they can be used to identify recent contaminants (bacteria, fungi, sample-mounting resins). In reflected white-light microscopy, the yellow-green/gray color of mature organic matter (Chen et al. 2015) is readily distinguished from organic contaminants and from oxide and sulfide minerals. In metamorphic carbonaceous matter, the presence and structure of atomic-scale ordering in HR-TEM images (e.g., Bernard et al. 2007) confirms pre-metamorphic precursors. Raman spectra can be used to quantify the maturity of organic matter, which is linked with burial conditions (Henry et al. 2019). The latter can also be estimated with mineral proxies. The agreement between organic and mineral “geothermometers” indicates that organic matter predates the most intense burial conditions.

Pseudofossils

Abiotic mineral and/or organic microstructures mimicking microfossil morphologies (such as filaments, spheres) and organizations, named biomorphs or pseudofossils, can be observed in rocks (Lepot 2020). Discriminating putative microfossils (dubiofossils) from abiotic biomorphs is difficult, as exemplified by the debate over the oldest candidate carbonaceous microfossils from the 3.46 Ga Apex Chert.

Based on 3D Raman and CLSM imaging, microfossils were inferred (Schopf and Kudryavtsev 2010). However, evidence that the reported carbonaceous filaments are associated with a continuum of shapes, which likely include, mineral mimics coated/impregnated with migrated organic matter, was shown by a combination of multiplane optical microscopy and TEM (Brasier et al. 2015 and references therein).

A number of criteria have been identified that can be combined with (often not individually) the textural features to help assess putative cellular microfossils (Lepot 2020). (1) A geological context allowing preservation of fossils. (2) The absence/presence of common biomorph templates such as quartz spherulites, or volcanic vesicles, which are best studied with optical microscopy. (3) The preservation of organic microstructures seen in petrographic sections (Fig. 1) and through demineralization of the host rock (observed with optical microscopy, Fig. 3, and SEM, e.g., Javaux et al. 2004), arguing for microfossils. (4) The identification of features such as folding/wrinkling that highlight postmortem deformability (e.g., lower picture in Fig. 3). These are best seen in SEM in demineralized, compressed or deflated microfossils, or in situ with CLSM in 3D microfossils (Fig. 1) (Schopf and Kudryavtsev 2010). (5) Continuous to sub-continuous organic matter that is disposed at the grain boundaries of its mineral matrix and that displays morphologies consistent with anatomic features such as cell walls and/or sheaths (Fig. 5) (Brasier et al. 2015; Lepot et al. 2017). The study of the textural relationship between minerals and organics can be assessed at the micrometer scale with Raman spectromicroscopy (Fig. 2). However, Raman spectromicroscopy cannot readily show the boundaries of adjacent grains/crystals with similar compositions and their relationships with carbonaceous matter. EBSD and/or a combination of STEM (Fig. 5a) and TEM-nanodiffraction mapping can outline adjacent crystals of similar compositions. Microtubular textures exemplified in Fig. 2, initially interpreted as the etching marks left by microorganisms (thus termed ichnofossils) in basaltic glass, have been reevaluated as metamorphic mineral textures using a combination of

Raman spectromicroscopy, NanoSIMS, and TEM (Lepot 2020). Finally, (6) observation of diagnostic cellular ultrastructures as detailed below can demonstrate microfossils.

Metals in Fossil Organic Matter

ToF-SIMS revealed increased metal concentrations in some early Paleozoic assemblages of chitinozoans, which coincides with, and may explain the malformations observed in the microfossils (Vandenbroucke et al. 2015). ToF-SIMS characterizes the surface of microstructures, although depths-profiles can be measured. Nano-S-XRF can characterize trace metals in the complete volume of cells (Lemelle et al. 2020). The presence of metals associated with fossil organic matter can partly explain contrasts in TEM images between distinct ultrastructures (in addition to variations in density), as discussed below. It also makes organic matter visible in TEM without requiring heavy-metal staining like that used for fresh/recent organic matter (Fig. 4, Lepot et al. 2014).

High-Resolution Morphological and Ultrastructural Information

Several morphological features can further demonstrate anatomical/cellular microstructures and assess their taxonomic relationship to extant or younger (micro)organisms. Combined thick and multilaminar cell walls can be seen in some demineralized organic microfossils with TEM (Javaux et al. 2004), but also in some organic microfossils preserved in their mineral matrix with CLSM (Fig. 1), SEM (Fig. 4; Wacey et al. 2017), or TEM. Such ultrastructures have been used to demonstrate an eukaryotic affinity. Cell-wall textures, for example, regular ornamentations and/or protrusions (processes) can be seen in optical microscopy, or highlighted with SEM (surface, or cross-section: Fig. 4) and CLSM, and are also diagnostic of eukaryotes (Javaux et al. 2004). Internal structures can be highlighted – in particular when the wall is dark – with CLSM in 3D (Fig. 1). CLSM and Raman imaging have been used, for example, to reveal the internal structure diagnostic of a comb-jelly (animal) embryo in 540 Ma phosphates (Schopf and Kudryavtsev 2010).

Evidence for Selective Molecular Preservation

The selective preservation of derivatives of various biomacromolecules is demonstrated by chemical heterogeneities between distinct taxa in the same rock analyzed by micro-FT-IR spectroscopy (Fig. 3). It is also supported by chemical heterogeneities shown by XANES at the nanoscale in a single microfossil (Bernard et al. 2007). NanoSIMS has been used to reveal organic N and S in 850 Ma-old microfossils (Oehler et al. 2006) that are usually not detected as functional groups in FT-IR spectra of microfossils (Fig. 3), possibly due to low abundances, or the high sensitivity of SIMS to these heteroatoms. Moreover, these NanoSIMS analyses documented distinct N/C ratios in filamentous versus spheroidal forms that might reflect different biological precursor, such as extracellular polysaccharide sheaths in filaments and cell walls in spheroids (Oehler et al. 2006).

These molecular compositions may represent a combination of biomacromolecules that evolved during burial diagenesis and metamorphism (if any), possibly with an addition through polymerization of free molecules such as lipids (Versteegh et al. 2004), hence forming “geomacromolecules.” Some molecular heterogeneities in rocks may be inherited from microscopically heterogeneous diagenetic conditions, such as sulfurization of organic matter linked with microbial metabolism, as evidenced with XANES and SIMS (Lepot 2020). Such heterogeneities in diagenetic conditions can be evaluated by the characterization of the petrographic context of the matrix hosting the microfossils, e.g., using SEM (Fig. 4) and Raman spectromicroscopy (Fig. 2).

Several examples of the use of molecular compositions to constrain the origin of specific groups of microfossils follow. The coupling of pyrolysis GC-MS and FT-IR ruled out the possibility that the dark-wall preserved in chitinozoans (Fig. 3) is derived from chitin, but is rather an aromatic-rich macromolecule for which the precursor remains unknown (Dutta et al. 2007). The preservation of derivatives of the biomacromolecule sporopollenin is shown in FT-IR spectra of spores of Silurian land plants, which contain a combination of strong aromatic and aliphatic signals together with

a specific band of aromatics only known in spores, peat, and lignite (Steemans et al. 2010). In contrast, some marine acritarchs, likely planktonic unicellular eukaryotes, display a dominance of long aliphatic chains in FT-IR (Fig. 3b), which are likely related to the preservation of algal macromolecules produced by algae (Steemans et al. 2010; Olcott Marshall and Marshall 2015). The CH_3/CH_2 ratio analyzed with FT-IR in microfossils of the Proterozoic preserved in their quartz matrix has been used to support the preservation of lipids produced by bacteria rather than archaea or eukaryotes (Igisu et al. 2009).

In all the cases above, molecular compositions appear useful for taxonomy in association with morphological/ultrastructural constraints. However, the detection of organic heteroatoms (N, S, O, P), of organic functional groups, or the identification of molecular formula may not be sufficient to rule out pseudofossils. Indeed, complex organic molecules may form abiotically, and migration of bio-sourced bitumen may form pseudofossils or coat mineral biomorphs (Lepot 2020). Association of distinct molecular compositions with specific morphospecies from a single rock (e.g., Fig. 3) can help demonstrate microfossils.

Constraints from C Isotope Ratios of Organic Matter

Organic carbon-isotope ratios ($^{13}\text{C}/^{12}\text{C}$) have been measured with SIMS for several microfossil assemblages and have been linked to the metabolic activity of the organisms (Orphan and House 2009; Williford et al. 2013; Lepot 2020). Heterogeneities in organic carbon isotope ratios measured between microfossils of the same taxon displaying different ultrastructural preservation (Williford et al. 2013) indicate that selective preservation may to some extent bias their C-isotope signature. Some C-isotope differences recorded among distinct microfossils preserved in the same rock are nevertheless too large to be explained by selective preservation and pointed to a distinction between eukaryotic and cyanobacterial precursors for two of the most common microfossils of the Neoproterozoic (Williford et al. 2013). It moreover implies that

the organic matter in these distinct microfossils could not have formed by filling of empty mineral molds by bitumen and that distinct macromolecules may be preserved in these fossils. C-isotope ratio heterogeneities distinguished among some of the oldest candidate microfossils (~ 3 and ~ 3.4 Ga) support their interpretation as anatomical remains and argue against an all-abiotic origin for the bulk of the carbonaceous matter in their host rocks (Lepot 2020).

Applications

As detailed above, three of the main applications of analytical techniques to microfossils target the link between organic matter and minerals (matrix, biominerals, diagenetic replacements). They help distinguish microfossils from pseudofossils, inspect the textural relationship between anatomy and candidate biominerals, and investigate post-mortem processes (e.g., mineral growths) leading to modifications of microfossil ultrastructures. Complete analysis of organic-mineral associations is achieved in TEM/STEM at the nanoscale in 2D following destructive sample preparation. CLSM and S-XRCT are particularly efficient for nondestructive 3D imaging of organics and minerals, respectively. It appears in turn necessary to combine multiple techniques on the same sample to investigate organic-mineral relationships in 3D. This is enabled by the advent of correlative microscopy, where all techniques record spatial coordinates and use automated sample displacements, together with spatially resolved analyses and novel sample preparation methods. These investigations can be further coupled with isotope-ratio microanalysis, and in situ mass-spectrometry of the molecular composition of fossils.

Future Directions

Optical microscopy and CLSM, followed by SEM provide nondestructive imaging. The analysis of mineral chemistries can be performed destructively in 3D with FIB-EDX (elemental mapping

by EDX during sequential ablation of a sample) or with nano-S-XRF, which is nondestructive. Observation of the disposition of grain boundaries is crucial in assessments of organic-texture templating, and the orientations of crystals can inform on (bio)mineral growth processes. These features can be imaged with EBSD in 2D and FIB-EBSD in 3D during sequential FIB ablation. In parallel, TEM can be performed on destructively prepared targets. This combination is expected to provide the highest level of textural-mineralogical information on microfossils.

Isotope ratio of C, N, and S can constrain metabolisms (Lepot 2020) and be measured with SIMS at the microscale by ablation of a few hundred nanometers of sample surfaces. This would be optimally performed between the nondestructive and the more destructive analyses listed above.

Spectroscopy including XANES and FT-IR demonstrate the preservation of distinct molecular signatures in some microfossils. Spectroscopy can thus be used in conjunction with SIMS of C, N, O, H isotope ratios to evaluate possible biases imparted by selective preservation processes on metabolic signatures. AFM-IR can investigate functional groups and ToF-SIMS the chemical formula of organics down to the nanoscale. These two techniques are essentially nondestructive beyond the initial preparation of ultra-flat sections, unlike the extraction of FIB sections for XANES or demineralization for FT-IR. As such, they can be the first analyses to be performed after initial microscopy, and can be followed by the 3D and/or destructive investigations. Nevertheless, initial preparation of ultra-flat rock surfaces requires stringent protocols to minimize contaminations (Fadel et al. 2020). ToF-SIMS has identified some bio(macro)molecules in macrofossils (Thiel and Sjövall 2015). Developments in the application of ToF-SIMS to microfossils is currently focused on overcoming the coupled limitations of superficial contaminations, topographic biases, and small amounts of organic matter. The combination of spatially resolved spectroscopies (XANES, FT-IR) and mass spectrometry (ToF-SIMS) is expected to provide important constraints on fossilization processes and the taxonomy of microfossils.

Inorganic species can be detected and semi-quantified with ToF-SIMS, and quantified with nano-S-XRF. This could help document trace metals in fossil-forming geomacromolecules, in order to provide clues on the enzymatic machinery of parent microorganisms and/or on environmental stressors (Vandenbroucke et al. 2015).

Definition

“Microgravity” (also commonly referred to as “Zero-G”) is broadly accepted as describing the condition of weightlessness experienced during spaceflight. More precisely, this unique physical state arises from an apparent lack of gravitational acceleration occurring relative to a local inertial reference frame, but does not necessarily refer to a reduced level of gravity in an absolute sense. The root term “gravity” in this case is actually a unit of acceleration, with Earth’s gravitational attraction of 9.8 m/sec^2 defined as $1 g$. The prefix “micro” can specifically indicate a factor of 10^{-6} or, more generally, just imply being very small.

Overview

“Microgravity” (also commonly referred to as “Zero-G”) is broadly accepted as describing the condition of weightlessness experienced during spaceflight, on a parabolic aircraft trajectory, or in a vertical drop tower. More precisely, this unique physical state arises from an apparent (or real) lack of gravitational acceleration that exists on a given mass relative to its local inertial reference frame (e.g., the spacecraft).

The root term “gravity” in this context refers to a unit of acceleration, with Earth’s gravitational attraction of 9.8 m/sec^2 defined as $1 g$. The prefix “micro” can specifically indicate a factor of 10^{-6} or, more generally, just imply being very small. Any multiple or fraction of this unit of acceleration can be expressed in relative terms of g , for example, an astronaut might experience $3 g$ ’s of acceleration during launch or $0.17 g$ on the lunar surface.

It is important to note that “microgravity” does not necessarily imply a reduction of the presence of gravity itself nor any change to the gravitational constant ($G = 6.672 \times 10^{-11} \text{ N}\cdot\text{m}^2\cdot\text{kg}^{-2}$), which is neither a force nor an acceleration per se, rather a physical constant used to dimensionally derive the force (F_{12}) resulting from the attraction of a mass (m_1) on another mass (m_2) a distance (r) away, defined as

$$F_{12} = (G m_1 m_2) r^{-2}$$

As a result of this force, gravity can produce two effects on an object – motion and weight. The familiar force (F) equation derived from this relationship, taking into account the acceleration (a) that acts on a given mass (m), reduces to

$$F = ma$$

When a mass (m) is resisted by an equal and opposite reaction, this force (F) defines weight. When an equal and opposite reaction is negligible, however, as occurs during orbital spaceflight or linear freefall in a vacuum, gravity instead gives rise to unimpeded (i.e., accelerated) motion, which is governed by either centripetal or linear

acceleration, respectively. As a consequence, no weight is imparted to the mass and, within its inertial reference frame, it experiences a state of weightlessness attributed to the lack of relative acceleration, termed microgravity. In contrast, a body falling through a viscous medium such as air or water reaches a state of terminal velocity where the force due to gravity is balanced by the resisting drag, at which point the body achieves a constant speed and experiences its full weight. For a spacecraft on a hyperbolic escape trajectory sufficiently far (r) from any dominant mass (m_1) such that no significant gravitational acceleration is affecting it, Newton's first law of motion dictates that it will continue moving at a constant velocity until acted on by an external force. In this unique case, the absolute presence of gravity theoretically approaches zero.

The microgravity environment experienced in Earth orbit has been used since the early 1960s to conduct studies on living organisms ranging from plants and microbes to humans. A wide variety of physical and biological responses to weightlessness have been characterized by this research.

Definition

MicroFUN (Microlensing Follow Up Network) is an informal consortium of observers dedicated to photometric monitoring of interesting microlensing events in the Galactic bulge. The primary scientific objective of MicroFUN is to observe high-magnification microlensing events in order to detect the signatures of exoplanets orbiting the primary lens. MicroFUN is somewhat unusual in that over half its members are amateur astronomers. MicroFUN has contributed to the discovery of the majority of the planets detected by microlensing. In 2008, MicroFUN announced the discovery (along with other collaborations) of the first planetary system discovered by microlensing, ► [OGLE-2006-BLG-109Lb,c](#). This system of two planets closely resembles a scaled analog of Jupiter and Saturn.

MOA

Definition

MOA (Microlensing Observations in Astrophysics) is a collaboration of astronomers from New Zealand and Japan that employs the microlensing technique to search for dark matter and exoplanets. The Principal Investigator of the MOA collaboration is Yasushi Muraki of Nagoya University. MOA has contributed to the discovery of nearly all of the planets discovered by microlensing. The MOA 1.8 m telescope is located at Mt. John Observatory on the south island of New Zealand.

Micrometeorites

Emmanuel Jacquet and François Robert
Institut de Minéralogie, Physique des Matériaux
et Cosmochimie (IMPMC), Sorbonne Université
et Muséum National d'Histoire Naturelle, UMR
7590 CNRS, Case 52-61 rue Buffon, Cedex
05 Paris, France

Definition

A micrometeorite is the remnant, on a planetary surface (e.g., Earth), of an interplanetary submillimeter-size dust particle.

Overview

The arrival on Earth of microscopic extraterrestrial grains has been discussed since the late nineteenth century for example, with the discovery of cosmic spherules by the Challenger oceanographic mission in 1872. These spherules were collected with a magnet by dragging the surface of marine sediments. The extraterrestrial origin of these spherules was nevertheless a subject of debate and was not accepted until the advent of ion microprobes in the late 1980s. Laboratory measurements of implanted rare gases, solar flare tracks, and isotope abundances confirmed that the collected particles are indeed extraterrestrial and that, prior to atmospheric entry, they spent up to several million years as small particles orbiting the Sun. Starting in 1982, micrometeoroids were collected in the Earth's stratosphere using plate collectors under the wings of NASA airplanes. These are referred to as *Interplanetary Dust Particles* (IDPs) in contradistinction to micrometeorites which have reached the ground. In the same decade, Michel Maurette pioneered the collection of micrometeorites in polar regions from melted ice and snow, first in Greenland and then in Antarctica, with present-day collections in Concordia snow (by his successor team in Orsay, now at the Muséum national d'Histoire naturelle) yielding the most pristine micrometeorites to date (if IDPs, which have only spent hours to weeks in the atmosphere, are set aside). Less favorable environments such as urban rooftops (e.g., Suttle et al. 2021) have also been more recently evaluated.

For Antarctic collections, knowledge of the melted volume and the snow precipitation rate allows to estimate the micrometeorite flux, typically on the order of 5 kt/a when extrapolated worldwide (e.g., Rojas et al. 2021). This is smaller than the 36 kt/a estimated from the space-based Long Duration Exposure Facility (Zolensky 2021) presumably because of ablation during

Interplanetary dust particles

atmospheric transit. In their size range (typically around 0.1 mm), micrometeorites can survive (depending on entry velocity and angle) because they are decelerated at high altitudes and thus suffer less heating and ram pressure than their macroscopic counterparts (because of the lower air densities). *Cosmic spherules* have entirely melted during atmospheric transit, but *fine-grained* (compact or fluffy) or *coarse-grained* (or crystalline) micrometeorites may show little evidence of thermal alteration during atmospheric transit; *scoriaceous* micrometeorites show an intermediate degree of melting. Micrometeorites should not be confused with (generally more oxidized) ablation spherules detached from macroscopic meteorites during atmospheric entry (e.g., Van Ginneken et al. 2010).

Most micrometeorites are chondritic and show affinities to carbonaceous chondrites even though the latter represent only 4% of meteorite falls. Indeed, micrometeorites are not biased toward the asteroid main belt between Mars and Jupiter as macroscopic meteorites are, because Poynting-Robertson drag (due to the recoil of impinging solar photons, Doppler-shifted because of orbital motion may incur inward drift from more distant regions (e.g., the Kuiper belt). Individual mineral grain sizes range from micrometers (primarily pyroxenes and olivines) to nanometers, with the predominant size for all phases less than 100 nm. IDPs, which are generally more pristine than micrometeorites fallen on the ground, have been classified into two main groups: Chondritic-Smooth (CS) IDPs, which show phyllosilicates, and Chondritic-Porous (CP) IDPs (corresponding to the “fine-grained fluffy” micrometeorites) which show anhydrous silicates (olivine, pyroxene). Both types of silicate assemblages are nevertheless sometimes observed together. CP IDPs contain submicron Glasses with Embedded Metals and Sulfides (GEMS) which have been entertained to be of presolar origin, although only a minority display anomalous isotopic signatures. Carbonaceous phases present in aggregates are disorganized organic polymers sometimes regarded as the products of a low-temperature organosynthesis in space such as Fischer-Tropsch synthesis (~530 °C). Some Antarctic micrometeorites are

dominated by organic matter and referred to as →UltraCarbonaceous Antarctic MicroMeteorites (UCAMMs).

Based on estimated entry velocities, it has long been believed that many CP IDPs are cometary. They are released into space by comets when they enter the inner solar system. Comets are made of up to 50% water ice that sublimates when they come closer and closer to the Sun, causing an increase in their surface temperature. This massive sublimation of water – along with many other volatile species – causes the injection of cometary dust into interplanetary space. Comets may have formed too late for radiogenic heating to bring about ice melting and aqueous alteration, which is consistent with the lack of hydrated phases in CP IDPs and fine-grained fluffy micrometeorites. Earth-crossing comets are known to produce annual meteor showers (such as the Perseids in mid-August), superimposed on background sporadic meteors. Some IDP collections have targeted such time windows in the hope of sampling the micrometeorite end of the size distribution of these cometary debris.

One space mission – *Stardust* – has collected particles directly from the coma of comet 81P/Wild 2 and has returned them to Earth. It was thus possible to study for the first time bona fide cometary grains from a known parent body with laboratory instruments that have better performances than instruments flown on spacecrafts (such as those which attended the 1986 return of the Halley comet). The Wild 2 grains bear resemblances to carbonaceous chondrites, and with some specific micrometeorites. Little evidence for aqueously altered material has been found, although the high-velocity capture would have preferentially destroyed that material. Since the available amount of micrometeorites greatly outweigh that of *Stardust* returned samples, they of course remain the chief resource for cometary matter research.

[Trace elements](#)

Definition

Micronutrients are elements, in general metals or metalloids, required in small amounts for cell growth. Micronutrients generally play a critical role as components of specific enzymatic activities. Not every micronutrient is required by all cells. The best known micronutrients are the following: chromium, cobalt, copper, manganese, molybdenum, nickel, selenium, tungsten, vanadium, zinc, and boron. For instance, boron is an inducer of quorum sensing; copper is required for photosynthesis or the activity of the enzyme cytochrome c oxidase and some superoxide dismutases; manganese is present in certain superoxide dismutases and in oxygenic photosynthetic systems; nickel can be found in most hydrogenases and in urease; selenium is present in formate dehydrogenases and in the amino acid selenocysteine; and zinc can be found associated to ► [RNA](#) and ► [DNA](#) polymerases and many DNA-binding proteins.

[Germ](#); [Microbe](#)

Definition

Etymologically, microorganisms are small organisms whose size is too small to be observed by the naked eye. The resolution of the human eye is 0.2 mm, and this establishes 1 mm as an artificial limit

for the maximum size of microorganisms. Taxonomically, “microorganism” lacks a precise meaning, and the term includes prokaryotes (► [Bacteria](#) and ► [Archaea](#)) and eukaryotes (protists, microscopic algae, and fungi), which are all unicellular or lacking true tissues. Exceptionally, ► [virus](#) should be included in the definition of “microorganisms,” even though they lack cellular arrangement. Microbiology is the area of biological sciences that studies microorganisms. Prokaryotes are the main focus of study in Microbiology. All are unicellular and lack a nucleus (pro-karion); their response to oxygen is very diverse; they can be auto- or heterotrophic and they employ the entire range of energy-obtaining systems found in living beings: anaerobic or aerobic respiration, ► [fermentation](#), chemolithotrophism, and oxygenic or anoxygenic photosynthesis. Phylogenetically they are divided into two Domains: *Archaea* and *Bacteria*.

Acronyms (Optional)

MOR

Definition

A midocean ridge is a submarine mountain range with a valley (rift) at its center. It corresponds to the divergent boundary between two tectonic plates (divergent plate boundary). Here the Earth’s crust is spreading, forming new ocean floor that gradually moves away from the ridge at a speed between 1 and 10 cm per year. Beneath the ridge, rising mantle material partially melts in response to reducing pressure. Produced ► [magma](#) is collected in a magmatic chamber a few kilometers below the seafloor. Much of the magma eventually freezes in place forming the bulk of the new ► [oceanic crust](#) composed of MOR ► [basalts](#) (or MORBs), ► [gabbros](#), and residual ultramafic rocks (harzburgite, dunite). Seawater circulates actively, reacting with the volcanic rock, dissolving out metals, and depositing them around seafloor high-temperature springs (black and white smokers). Midocean ridges are the main source of acidity for the ocean. Fractures filled with heated water act as incubators for microbes that live in some of the harshest conditions ever discovered to support life. Conditions typical at MOR have been often depicted as one of the possible environments where life flourished on the Earth during the ► [Hadean](#).

Mie Scattering

Emmanuel Marcq
LATMOS/IPSL, UVSQ Université Paris-Saclay,
Sorbonne Université, CNRS, Guyancourt, France

Keywords

Scattering: Elastic · Far field · Polarizing

Synonyms

[Lorenz-Mie-Debye scattering](#); [Lorenz-Mie-Debye solution](#); [Mie solution](#)

Definition

Solution to the problem of radiation scattering by a homogeneous dielectric sphere. It yields a realistic model of scattering by spherical (e.g., liquid) droplets found in some atmospheric clouds, as well as a convenient first-order approximation for nonspherical scatterers also found in planetary clouds and/or hazes, bridging the gap between the small scatterer approximation (Rayleigh scattering) and large scatter approximation (geometric optics). Compared to Rayleigh scattering, Mie

scattering is weakly wavelength dependent and weakly polarizing.

Overview

Hypotheses

Mie scattering (more properly known as *Lorenz-Mie-Debye theory of light scattering*) relies on the following assumptions:

- The scattering particle is a homogeneous, dielectric sphere of radius r .
- Incident radiation is a monochromatic plane wave of wavelength λ .
- Only *far field* solutions are considered (terms vanishing faster than d^{-2} are discarded).

August Mie, based on previous work by Lorenz and others, showed (Mie [1908](#)) that the formal solution for the scattered electromagnetic could be expressed as an infinite series depending only on:

- The *size parameter* x defined as $x = \frac{2\pi r}{\lambda}$
- The scattering angle Θ , due to the axisymmetry of the problem
- The complex refractive index $m = m_r + i \cdot m_i$ of the dielectric sphere (relative to the surrounding medium)

The exact expression and mathematical derivation are highly technical and can be found in several radiative transfer textbooks (Liou [2002](#)). They are beyond the scope of this short overview.

Limits

Assuming $m_i = 0$ and keeping the first order of the Taylor expansion with respect to x (which is valid for small particles $r \ll \lambda$) yields back all results from the ► [“Rayleigh scattering”](#) model (see linked entry). Mie scattering can therefore be thought as one possible way to generalize Rayleigh scattering for arbitrary scatterer sizes and imaginary refractive index.

The other limit $x \gg 1$ yields back the results from *geometrical optics* (raytracing multiple reflections and refractions found in, e.g., rainbows).

Extinction

Extinction Efficiency

Defining the *extinction efficiency* coefficient as $Q_{\text{ext}} = \sigma_{\text{ext}}/\pi r^2$ (i.e., the ratio between the extinction and geometrical cross sections), Mie theory yields the values of Q_{ext} plotted in Fig. 1.

Several features are especially noteworthy:

- The maximal value of Q_{ext} is reached for $x \approx \frac{2}{m_r - 1}$, and can reach values well above unity. In other words, and for usual values of m_r , **Mie extinction is most efficient when the**

radius of the particles is similar to the incident wavelength.

- The Rayleigh limit ($x \ll 1$) yields the familiar $Q_{\text{ext}} \propto \lambda^{-4}$ dependency. For larger values of x , this slope disappears, resulting in a more or less “grey” scattering as opposed to the typical “blue” prevalent in Rayleigh regime.
- The geometrical optics limit ($x \gg 1$) yields $Q_{\text{ext}} \rightarrow 2$, which seems counterintuitive. This is because, as previously mentioned, Mie solution is a far field solution, so that the angular size of the scattering particle is kept small relative to the observer. Therefore, diffraction

Mie Scattering,

Fig. 1 Left: extinction efficiency vs. size parameter and real refractive index according to Mie theory. The dotted red line follows $r = \frac{\lambda}{\pi(m_r - 1)}$. Right: extinction efficiency (solid) and single scattering albedo (dashed) vs. size parameter for several imaginary refractive indices

cannot be neglected, and results in doubling the purely geometrical cross section.

- Increasing imaginary refractive index smoothes the $Q_{\text{ext}} = f(x)$ function, since higher-order interferences are suppressed with increasing absorption in the dielectric medium.

Finally, for realistic size distributions of scattering particles, the convolution of the interference pattern by the size distribution results in smoothed variations of the Mie parameters (Q_{ext} , ϖ_0 , phase function, etc.). Actually, size distributions sharing a given modal radius and variance yield very similar Mie computations, the influence of higher-order size distribution moments becoming negligible.

Single Scattering Albedo

Without any absorption within the dielectric sphere ($m_i = 0$), Mie theory yields $\varpi_0 = 1$ as expected. As can be seen in Fig. 1, increasing m_i causes absorption, and therefore $\varpi_0 < 1$ in this case. Actually, $m_i > 0$ yields $\varpi_0 \rightarrow 1/2$ for $x \gg 1$: in the geometrical optics limit, the particle acts as an absorber over its geometrical cross section, leaving only the diffracted component. Also, $\varpi_0 \rightarrow 0$ for $x \ll 1$ provided $m_i > 0$.

Phase Function

As can be seen in Fig. 2, the phase function behavior is highly dependent on the size parameter. For small values of x , Rayleigh phase function is recovered with an asymmetry parameter $g = 0$ (refer to ► “Radiative Transfer” entry for a definition of asymmetry parameter g), then g increases with increasing x , with the appearance of a strong forward scattering peak (near $\Theta = 0^\circ$) as well as increasingly complex interference patterns. In the geometrical optics limit, these interference patterns yield successive rainbow orders (single or multiple refraction/reflection of incident rays within the spherical droplet).

Polarization

Mie scattering, like Rayleigh scattering, can induce linear polarization of the scattered radiation, as can be seen in Fig. 2. Here also, $x \ll 1$ yields back the familiar Rayleigh polarization

pattern ($\approx 100\%$ for $\Theta = 90^\circ$), whereas more complex, interferential patterns in polarization appear at larger values of x . Especially, the negatively polarized backscattering peak centered on $\Theta > 150^\circ$ and $x > 2.5$ is known as the *glory* phenomenon.

Finally, one should note that multiple scattering tends to blur and reduce polarization in the scattered radiation, due to the uncorrelated random geometries of successive scattering events.

Applications in Planetary Atmospheres

Although the Mie solution was discovered in the early twentieth century, using it in practice was only possible once computers allowed for a summation of a large enough number of terms among the infinite series. Moreover, since the angular dependency of the terms is already expressed by Legendre polynomials, it is especially suitable for use in a discrete ordinate radiative transfer model. A well-known Fortran implementation of Mie solution is due to Bohren and Huffman (1983).

In Solar System

Spectropolarimetry is an especially valuable tool to investigate the scattering properties of a planetary atmosphere, since it allows for the exploration of a larger parameter space (Θ and x , thanks to varying wavelength), as well as accessing both intensity and (at least) the linear degree of polarization. Comparison of these observations with Mie theory then leads to useful constraints on both scatterers size distribution and refractive index (and therefore composition). Taking polarization into account (as opposed to the only scalar intensity) leads to an increased sensitivity to the microphysical properties of the scattering particles, since polarization depends mainly on the first few scattering orders.

As an illustration, a famous successful application of Mie theory, Hansen and Hovenier (1974) was the identification of the clouds of Venus as primarily composed of $1\text{ }\mu\text{m}$ liquid droplets of a highly acidic $\text{H}_2\text{SO}_4\text{--H}_2\text{O}$ solution ($>75\%$ H_2SO_4). Similar ground-based studies of the scattering phase function of outer planets are hampered by the small variation range of Θ as seen from Earth.

Mie Scattering,

Fig. 2 Left: logarithmic polar plots of Mie phase function for some size parameter values, $m = 1.5$ and unpolarized incident beam; right: degree of linear polarization with respect to scattering angle and size parameter for an unpolarized incident beam

M

For Exoplanetary Atmospheres

In transit spectroscopy, Mie scattering manifests itself as a more-or-less spectrally uniform transit depth “floor” in cloudy atmospheres. It is especially noticeable at larger wavelengths (near IR onwards), since Rayleigh scattering by the gaseous atmosphere tends to dominate at smaller wavelengths.

In the near future, (spectro) polarimetry could be a valuable tool for detecting highly scattering exoplanetary atmospheres in the Rayleigh-Mie

regime, since the scattered component would exhibit periodic variations of its polarization as a function of orbital phase angle, whereas the stellar component would be only weakly polarized.

Limitations

Mie scattering is a powerful tool for computing light scattering by spherical particles, but not all aerosols match this assumption: ice crystals, mineral dust, and photochemical hazes are sometimes far from spherical. In such a case, other, more

sophisticated calculation methods should be used for a quantitative analysis (*T*-matrix, discrete dipole approximation, finite elements, etc.), although Mie theory may still be used as a convenient, first-order approximation to derive, for example, the typical size of scattering particles.

Mildly Reducing Atmosphere

Henderson James Cleaves II
 Earth-Life Science Institute (ELSI), Tokyo
 Institute of Technology, Tokyo, Japan
 Blue Marble Space Institute of Science,
 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

A mildly reducing atmosphere is an atmosphere containing small but significant amounts of

reduced gases, for example, H₂, CH₄, NH₃, H₂S, or CO, and not containing a counterbalancing excess of oxidized species such as O₂. Many believe that the prebiotic Earth's atmosphere may have been mildly reducing due to mantle outgassing prior to the advent of biological oxygenic photosynthesis. In general, reducing atmospheres appear to be more favorable for the abiotic synthesis of organic compounds.

MW

Definition

The Milky Way is the galaxy where our Solar System is located. It consists of baryonic matter (stars, gas, and dust) but mainly of dark matter that is gravitationally bound to the baryonic matter.

Overview

The Milky Way (MW) is a spiral galaxy with an approximate mass of $1.3 \times 10^{12} M_{\odot}$, where roughly $10^{11} M_{\odot}$ is baryonic matter ($\sim 6 \times 10^{10}$ in stars and the rest in gas and dust), distributed in three main visible components: disk, bulge, and halo, all of them centered at the nucleus of the MW.

The disk is a flat rotating structure made up of stars and gas and present two main substructures: a thin disk and a thick disk. The thin disk is where the cold gas and dust are located and the new stars form, these new young stars form spiral arms (S shaped) that are bright relative to the disk, and they inspired the name of spiral galaxy. For this disk, the stellar and gas masses are $3.5 \times 10^{10} M_{\odot}$ and $1.2 \times 10^{10} M_{\odot}$, respectively; its maximum radius may be 30 kpc and its height from the galactic plane decreases with the radius, being 300 pc height at the galactocentric radius where the Sun is situated. The Sun is located at 8.2 kpc from the Galactic center and 25 pc height, inside the interior edge of the Orion-Cygnus spiral arm. The vast majority of thin-disk stars are younger than 9 Gyr and metal rich, show iron abundances (Fe/H) larger than 1/4 of the solar value and lower α /Fe ratios, and move in coplanar and circular orbits. The thick disk is more diffuse, thicker, and shorter than the thin disk. Its stellar mass is $6 \times 10^9 M_{\odot}$, the mean height at the solar position is ~ 900 pc, and its length is still unknown. This disk is formed only by stars older than 9 Gyr that move with less organized orbits. The iron abundances are higher than one tenth of the solar one, and for similar thin-disk Fe/H values, stars in the thick disk show higher α /Fe values.

The bulge is a dense quasi-box structure of 1.5 kpc in height contained within a radius of 3 kpc about the center of the MW. Its baryonic mass is $1.5 \times 10^{10} M_{\odot}$ and is made of metal-rich stars older than 11 Gyr with a mean iron abundance one quarter higher than the solar value and α /Fe similar to the thick disk stars. Most of these stars move in box/peanut orbits shaping the bulge.

The halo is a quasi-spherical structure formed by an inner stellar component and an outer

gaseous one. The stellar halo contains several substructures, extends beyond the thick disk to ~ 30 kpc radius, and presents a stellar mass $\sim 1.3 \times 10^9 M_{\odot}$. The halo stars show chaotic orbits in different directions and orientations and are metal poor with ages higher than 10 Gyr, with iron abundances lower than one tenth of the solar value and α /Fe similar to the thick-disk and the thin-disk stars. The gas halo extends farther than the stellar halo and is made of a hot and diffuse gas with an estimated mass of $2.5 \times 10^{10} M_{\odot}$ inside 280 kpc radius.

Inside the thick disk, halo, and bulge, there are globular clusters. These stellar clusters are small groups of high concentration with typical radii and masses of ~ 4 pc and $\sim 5 \times 10^5 M_{\odot}$, respectively. Most of them are formed by old and metal-poor multiple populations that present peculiar chemical abundance patterns.

All the previous baryonic structures are contained inside a $1.2 \times 10^{12} M_{\odot}$ dark matter halo, that is, a spherical hypothetical structure which extends beyond the stellar halo, probably up to ~ 300 kpc. This halo is made of non-baryonic matter whose nature remains unknown and which only interacts with itself and the baryonic matter through gravitation.

Up to date, it is unknown how the MW formed. For the most accepted theories based on mergers of small galaxies at different evolutionary stages, within the cosmological theory of cold dark matter, see →Galactic Archaeology.

Miller, Stanley

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

History

In 1953, the young chemist, Stanley Miller (1930–2007), published in *Science* a paper entitled “A production of Amino Acids Under Possible Primitive Earth Conditions.” His work was based on Harold Urey’s assumption about the reducing composition of the primitive atmosphere as well as on Oparin’s and Bernal’s previous suggestions.

In an apparatus built to circulate a mixture of CH₄, NH₃, H₂O, and H₂ exposed to electric discharges during 1 week, he noticed the production of amino acids (glycine, α alanine, and β alanine).

Miller’s paper constituted one of the most important events in the history of the researches on the origins of life. Miller’s result found an important audience in the scientific community as well as in the public opinion. His discovery was said to be the first step of the process of origins of life in earth.

Along with Urey, Miller’s was considered as one of the main inventors of prebiotic chemistry. During at least two decades, his work influenced conceptions of prebiotic conditions in which all experiments had to be done, and especially it imposed the idea of the reductive primitive atmosphere, without CO₂. Miller’s career was one of

the most active on the topic of the origins of life during the second part of the twentieth century.

Mimas

Therese Encrenaz

XLESIA, Observatoire de Paris - Section de Meudon, Meudon, France

Definition

Mimas, the innermost mid-sized satellite of ► [Saturn](#), was discovered by William Herschel in 1789. Its distance to Saturn is 185,600 km or only 3 Saturnian radii. The diameter of Mimas is 400 km and its density is 1.14 g/cm³, consistent with a body dominated by water ice. Mimas is heavily cratered; its largest impact crater, named Herschel, has a diameter of 130 km, or about a third of the satellite’s diameter. The perturbations induced by Mimas are believed to be responsible for the clearing of the Cassini division in Saturn’s rings. Mimas was first explored by the Voyager mission in 1980–1981 and later by the ► [Cassini](#) orbiter, which began to monitor the Saturn system in 2005.

Definition

A *mineral* is a naturally occurring solid of inorganic origin, with a definite chemical composition and in most cases an ordered atomic arrangement. Compositions range from pure elements like gold (Au), diamond (C), or native copper (Cu) to simple oxides (SiO_2 – quartz; TiO_2 – rutile) or carbonates (CaCO_3 – calcite) to highly complex silicate minerals (e.g., tectosilicate such as K-bearing feldspar KAlSiO_3). Silicate minerals dominate most parts of the solid Earth, the exception being the core which is composed mainly of Fe-Ni alloy. Most minerals are crystalline, but some, like chalcedony or opal, are amorphous. Assemblages of different minerals compose a rock.

Mineral Vesicles

Raffaele Saladino

Department of Ecological and Biological
Sciences, University of Tuscia, Viterbo, Italy

Keywords

Mineral vesicles · Abiotic mineral
precipitation · Heterogeneous catalysis ·
Prebiotic chemistry

Synonyms

[Silica metal oxide vesicles](#)

Definition

Mineral vesicles are self-organized biomimetic structures that form via abiotic mineral precipitation.

History

Mineral vesicles are self-organized biomimetic membranous structures that form in serpentinization-driven silica-rich water via fluid-rock interaction and mineral precipitation (Getenet et al. [2020](#)).

This process is expected to be a common phenomenon on primitive Earth and Earth-like planets characterized by alkaline environments García-Ruiz et al. (2017). In addition, mineral vesicles may resemble the geochemical conditions of Hadean Earth, when alkaline silica-rich oceans evolved from the early atmosphere and hydrosphere (García-Ruiz and Otálora 2015). These vesicles are able to catalyze prebiotic reactions, including the synthesis of molecules of biological relevance from simple chemical precursors such as formamide (Mattia Bizzarri et al. 2018). In this latter case, they act as heterogeneous catalysts more efficient than their “chemical garden” counterparts (Saladino et al. 2016), highlighting the beneficial role of the surface/volume ratio on the control of the overall kinetics of the reaction (Saladino et al. 2019). During the prebiotic reaction, mineral vesical growth and collapse release their molecular content in the bulk of the solution.

Modelling Terrestrial Planetary Atmospheres

Robin Wordsworth

School of Engineering and Applied Sciences,
Department of Earth and Planetary Sciences,
Harvard University, Cambridge, MA, USA

Keywords

Fluid dynamics · Radiative transfer · Convection · Clouds · Atmospheric chemistry · Planetary boundary layer · Hydrology · Biosphere · Ocean-atmosphere coupling · Albedo · General circulation model

Definition

Terrestrial planet atmospheric modelling is the process of quantitatively describing the physical and chemical behavior of the atmospheres of planets that are predominantly rocky in composition. It is performed to interpret *in situ*, satellite and telescope observations of Earth, other solar system planets and exoplanets. Model results influence multiple fields of research including geology, biology, and environmental science, as well as spacecraft mission planning.

History

Qualitative attempts to model terrestrial planet atmospheres goes back as least as far as the seventeenth century, when natural philosophers such as Edmund Halley began to build physical theories of the circulation of air in Earth's tropics. Halley's ideas were built upon by George Hadley in the eighteenth century, who first proposed the theory of Earth's trade winds based on conservation of angular momentum that now bears his name. Progress on understanding the atmospheric *greenhouse effect* (the trapping of infrared radiation that maintains Earth's habitability) occurred more slowly, with the first major steps forward made by Joseph Fourier in the nineteenth century.

A modern quantitative understanding of planetary climate and atmospheric chemistry only became possible after the development of quantum mechanics in the late nineteenth and early twentieth century. Experiments by John Tyndall and others demonstrated the infrared absorption features of water, carbon dioxide, and other molecules, but the development of Planck's Law for blackbody radiation and an understanding of quantum spectroscopy made rigorous climate science possible by the early twentieth century. The mid-twentieth century also saw several important developments in atmospheric fluid dynamics that laid the foundation for much modern understanding, including the concepts of potential vorticity, baroclinic and barotropic instability, and Rossby wave propagation. In atmospheric chemistry, early twentieth century experiments by Fabry, Buisson, Dobson, and others indicated the presence of an ozone layer in Earth's atmosphere, and models of its chemistry began to be developed from the 1930s onwards.

Investigation of the atmospheres of terrestrial-type planets beyond Earth started centuries ago, but did not make substantial progress until the advent of the space race in the middle of the twentieth century. Mars' atmospheric properties were studied by astronomers such as Herschel as long ago as the eighteenth century, but quantitative analysis and modelling of its atmosphere began in the 1960s, when the first global circulation models (GCMs) were developed and

photochemical analyses were performed. Venus' high surface temperatures were deduced from a combination of microwave observations by Earth-based telescopes and simplified atmospheric modelling in the early 1960s. Our understanding of Titan's atmosphere grew more slowly, with detailed models of its chemistry and climate emerging in the 1980s following flybys by Pioneer 11 and Voyager 1. Over the last few decades, a combination of data from new missions and advances in numerical techniques have led to numerous advances in modelling. The emergence of the field of exoplanet research has led to huge growth in the area of comparative planetology, and a growing number of modelling studies now focus on understanding terrestrial planets in a generalized way, rather than on simulating individual objects.

Overview

Modeling terrestrial planetary atmospheres requires a diverse array of tools, ranging from very simple to very complex. Because the composition and physical state of atmospheres depends on a host of different processes, incorporation of a wide range of physical, chemical, and biological effects is required in models depending on the problem of interest. Atmospheric modelling informs our understanding of a range of vital problems in planetary science, including anthropogenic global warming on Earth, the CO₂ cycle and atmospheric stability on Mars, the behavior of organic hazes on Titan, and the nature of ancient climates on Earth, Mars, and Venus. Observational constraints remain scarce for terrestrial-type exoplanets, but a combination of modelling and observations is going to vastly increase our knowledge of these objects in the coming decades.

Basic Methodology

The methodologies involved in modelling terrestrial planet atmospheres are highly diverse. The simplest modelling approaches can be purely

analytical, such as when equilibrium temperature is estimated for newly discovered exoplanets. On the other end of the scale, the most complex and numerically intensive approaches involve high-resolution simulations of entire planetary atmospheres in three dimensions (Fig. 1) including fluid dynamics, radiative transfer, atmosphere-ocean coupling, biosphere interactions, and other complex effects. Generally speaking, there is no right or wrong level of model complexity: the choice depends on the problem at hand and the nature of the observational constraints. *Hierarchical* modelling approaches are increasingly common, particularly for problems involving atmospheric fluid dynamics. In a typical hierarchical approach, an observed phenomenon is first investigated using a complex numerical model, and then a range of simpler models is used to replicate the key results as a way to test understanding of the underlying mechanism. Atmospheric modelling methodologies can be conveniently divided up into several categories based on the physics and/or chemistry they incorporate, as described in more detail below.

Radiative Transfer

Any planet's atmosphere interacts with electromagnetic radiation from its host star and from internal sources. The shortest wavelength stellar radiation dissociates and ionizes molecules in the upper atmosphere, driving atmospheric chemistry and causing escape of some chemical species to space. Longer wavelength radiation penetrates deeper into the atmosphere, causing warming when it is absorbed. In atmospheres like Earth's that are relatively transparent at visible wavelengths but opaque at longer infrared wavelengths, the trapping of upwelling infrared radiation and reemission higher in the atmosphere gives rise to the greenhouse effect. In some other cases, such as Titan, absorption of solar radiation higher in the atmosphere and subsequent cooling of the surface relative to the clear-sky case causes a so-called *anti-greenhouse effect*.

The most comprehensive and accurate approach to modelling radiative transfer in planetary atmospheres randomly selects individual photons and tracks their motion. This *Monte*

Modelling Terrestrial Planetary Atmospheres,

Fig. 1 Left: Output from an early general circulation model (specifically, zonally averaged temperature as a function of latitude and pressure/altitude; Manabe et al. 1965). Right: Output from a modern general circulation model (specifically, precipitable water on a single day in 2090 predicted by the Community Atmosphere Model, from the NASA Visible Earth Project)

Carlo method is reliable and in principle highly accurate, but it is too computationally costly to be used in climate simulations or in most retrievals of observational data. More commonly, the full radiative transfer equations are approximated to allow propagation in a limited number of directions only. In climate studies, the most common approach of all is a two-stream calculation, where the only permitted radiation directions are upward and downward.

The infrared absorption spectra of typical greenhouse gases such as CO_2 and H_2O are extremely complex, with large numbers of overlapping spectral lines due to coupled vibrational and rotational quantum transitions. Large spectral

databases such as HITRAN exist to permit the calculation of atmospheric absorption spectra (Fig. 2) at high resolution as a function of composition, pressure, and temperature. Once these spectra have been calculated, they can either be used directly in radiative transfer calculations (the “line-by-line” approach) or to calculate heating rates indirectly via approximations such as the correlated- k approach. An even simpler approach that is particularly useful for idealized simulations is to assume uniform atmospheric absorption at all thermal wavelengths (the “gray gas” model). Whatever the approximation, any radiative calculation is only as good as the absorption data it uses, and in recent years, much effort has been

Modelling Terrestrial Planetary Atmospheres, Fig. 2 Top: Infrared absorption cross-sections for a range of plausible greenhouse gases in an early martian atmosphere with an assumed 1-bar CO₂ atmosphere.

Bottom: Outgoing longwave radiation for a pure CO₂ atmosphere and for the same atmospheric composition as above, as simulated by a high spectral resolution radiative-convective climate model. (From Wordsworth (2016))

M

expended to improve the quality of absorption data for a large number of species over wide ranges of pressure and temperature appropriate to both solar system objects and exoplanets.

Atmospheric aerosols (e.g., condensate clouds, dust, and hazes) can have a profound effect on atmospheric radiative transfer and must also be taken into account in modelling calculations. Aerosols are particularly problematic for exoplanets, where frequently even their composition is unknown. For liquid aerosol particles of uniform composition and known refractive index, Mie theory can be used to calculate scattering and absorption properties. For more complex non-spherical and/or heterogeneous composition particles (e.g., water ice crystals on Earth or fractal tholin hazes on Titan), more complex modelling techniques are needed and the uncertainty in aerosol properties remains a challenge.

Planetary-Scale Fluid Dynamics

The large-scale motion of a terrestrial planet's atmosphere is ultimately driven by heating from

stellar radiation absorbed either at the surface or sometimes in the atmosphere itself. Aspects of this motion are usually highly nonlinear and chaotic, leading to sensitive dependence on initial conditions (the “butterfly effect”) that renders accurate long-term prediction of detailed behavior impossible. Nonetheless, large-scale flow features such as the Hadley circulation are generally much more robust and predictable. Often, planetary circulation modelling is performed in three dimensions using a computer program that solves an appropriate set of equations for conservation of fluid mass, momentum, and energy subject to source and sink terms and boundary conditions at the planet's surface and “top of the atmosphere,” which is usually defined as a fixed minimum pressure level. A wide variety of numerical techniques are used solve these equations, including finite difference, finite volume, and spectral approaches. Most modern codes are now adapted for parallelized computation, allowing much higher model spatial resolution than was possible in the past.

Simplified models that solve fluid equations in a few shallow layers only or for some restricted portion of the flow (e.g., the longitudinally averaged winds) also exist and are frequently used when deep understanding of the driving processes is sought after. Various diagnostic techniques such as eddy-mean flow decomposition, instability analysis, and spectral decomposition are also commonly used to analyze the nature of the flow in different regimes. Because terrestrial planetary atmospheres usually obey the ideal gas law fairly closely, treatment of dry thermodynamics is generally simpler than in gas giant simulations or planetary interiors (although exceptions exist, such as in the deepest portions of the Venusian atmosphere).

Volatile Cycles

The inclusion of radiative transfer and fluid dynamics processes in atmospheric models allows predictions of seasonal and regional changes in climate once a planet's orbit, rotation rate, and key surface properties (e.g., topography, visible reflectivity, thermal inertia) are taken into account. For a planet like Earth, however, these predictions will not be accurate unless another major set of processes is taken into account: the water cycle. More broadly, other solar system bodies have different condensable substances that undergo volatile cycling, such as CO₂ and H₂O on Mars, CH₄ on Titan, H₂SO₄ on Venus, and N₂ on Pluto. In all cases, the presence of a condensable species adds considerable complexity to atmospheric behavior.

Modern general circulation models treat condensables as tracer species that are actively tracked in time and space and allowed to evolve according to advective transport processes, turbulent sub-grid-scale “diffusion” and thermodynamic phase changes. Moist convection, the process by which condensables like H₂O are transported vertically in a planet's atmosphere, is a notoriously complex process that remains a significant source of uncertainty in climate models. Typically, the spatial resolution of global climate models is too low to resolve moist convection directly, so parameterizations must be used, although so-called “super-parameterized” models that replace the standard parameterizations with sub-

grid-scale 2D cloud-resolving models are becoming more widely used (e.g., Khairoutdinov and Randall 2001).

Beyond the complexity of moist convection itself, another major source of uncertainty arises from the *microphysics* of volatile condensation and evaporation processes (i.e., physics which occurs <1 mm scale). The size distribution of particles in a cloud is of fundamental importance for evaluating its lifetime, its radiative properties (which impacts climate), and the rate at which it produces precipitation (rain or snow). However, the way in which cloud particle size distributions vary with planet type, atmospheric composition, and other factors is still poorly understood. It is still common for general circulation models to assume a single fixed average cloud particle size, even in exoplanet and solar system paleoclimate simulations. On present-day Earth, much of the uncertainty in future climate change predictions comes from cloud behavior (Boucher et al. 2013).

Planetary Boundary Layer Modeling and Mesoscale Simulations

As was previously noted, planetary atmospheres are typically highly turbulent, and global models of the atmospheric circulation are never capable of resolving this turbulence down to the smallest scales. This is particularly important in the lowest portions of the atmosphere, the *planetary boundary layer* (PBL), where mechanical drag, convection and fluxes of volatiles, trace chemical species, and aerosols like dust connect the surface to the atmosphere. Planetary boundary layers are complicated but the theory of how they behave over a wide range of conditions is now well established. The behavior of Earth's planetary boundary layer is particularly well-constrained by observations, but PBL data also exists for other planets, such as Mars. Planetary boundary layer parameterizations in global climate models are based on turbulence similarity theories and closure schemes of varying complexity (e.g., Mellor and Yamada 1982). They are generally regarded as fairly reliable, although under certain conditions, such as the strong thermal inversions that occur in polar night or on the dark side of

tidally locked exoplanets, difficulties still occur (Joshi et al. 2020).

Mesoscale models, as the name implies, are models of the atmosphere that are localized to a domain that is intermediate in scale between the entire planet and the smallest scales. The definition varies, but a typical mesoscale model for Earth might cover a domain of 500×500 km in the horizontal and 15 km in the vertical. Mesoscale models sacrifice the ability to provide a global view on annual to decadal timescales, but in return they provide a wealth of information on turbulent and convective processes, which they are able to resolve to a far greater extent than global models. Mesoscale climate models are frequently used on Earth for weather prediction and fundamental research, and have also been applied to Mars and Titan (e.g., Spiga and Forget 2009). Their use as unique tools to enable insights into atmospheric processes that cannot be captured by global models is likely to grow considerably in the future.

Atmospheric Chemistry

The chemistry of terrestrial planet atmospheres is both fascinating in its own right and of immense importance to astrobiology, because it determines the robustness of atmospheric *biosignatures*. For most terrestrial planets, atmospheric chemistry is heavily influenced or dominated by photochemical processes, i.e., the photodissociation of molecules in the upper atmosphere by ultraviolet stellar photons. Classic examples of photochemical processes include the production of ozone on the modern Earth, the CO_2 photodissociation cycle on Mars, and the formation and evolution of organic hazes in the atmosphere of Titan. Modeling these processes requires accurate data on the ultraviolet cross-sections of all key molecules present in the upper atmosphere and kinetic data on the most important reactions between chemical species and radicals. Obtaining and validating this data is a continuing challenge, particularly in an exoplanet context, and species as well-known as H_2O continue to produce surprises (Ranjan et al. 2020).

The governing equations for atmospheric chemistry are frequently stiff in the numerical

sense, which means that solvers for these systems must be chosen carefully. The simplest atmospheric chemistry models are zero-dimensional (the box model approach), although one-dimensional models that allow for vertical transport of species are more common (Fig. 3; Nair et al. 1994; Segura et al. 2003). While computationally expensive, three-dimensional atmospheric chemistry modeling can also be very informative when the fidelity of observations justifies it. In this case, every long-lived chemical species must be treated as a tracer in the model, subject to advection by winds and chemical reactions at every grid point and time step.

Additional challenges arise when heterogeneous chemical processes are important, i.e., processes that couple aerosol phase (liquid or solid) chemistry with the gas phase. Such processes have been studied fairly intensively on Earth, but

Modelling Terrestrial Planetary Atmospheres, Fig. 3 Simulated atmospheric temperature (top) and ozone number density (bottom) as a function of star type for an Earth-like exoplanet, as simulated by a coupled radiative-convective/photochemical model. (Reproduced from Segura et al. (2003))

our understanding of their importance is much less well developed for other solar system planets (not to mention for exoplanets). Laboratory experiments play a particularly important role in determining production pathways and mechanisms in this context, although many uncertainties remain, particularly for the complex organic haze formation in Titan's atmosphere (Trainer et al. 2006; Hörst et al. 2012).

Upper Atmospheres

The highest regions of planetary atmospheres are of inherent interest because of the unique physics and chemistry that occurs there. They are also particularly important to long-term atmospheric evolution, because their behavior determines the rate at which the atmosphere escapes to space. Upper atmosphere models present special challenges because radiative transfer at these altitudes is often far from local thermal equilibrium, which necessitates more complex or more approximate methods to calculate heating rates. Other effects such as thermal conduction, gravity wave propagation and breaking, and ionization of the gas and interaction with the planet's magnetic field (if it has one) are also frequently important. Finally, rapidly escaping atmospheres may cease to be in hydrostatic equilibrium, which requires fluid dynamical solvers that are quite different from the type typically used to simulate the lower atmosphere. Upper atmosphere models of varying complexity have now been developed for most solar system planets and moons. Upper atmosphere modeling is also frequently performed for exoplanets to assess long-term evolution, although the scarcity of direct observational constraints for exoplanet upper-atmosphere models remains a major issue.

Biosphere-Atmosphere Couplings

A particularly interesting complication in modeling Earth's atmosphere occurs due to interactions with the biosphere. Many types of biosphere-atmosphere couplings exist, but on human timescales (years to centuries), links between vegetation and hydrology, the carbon cycle and human activities are particularly important. On geological timescales, the biosphere

strongly influences atmospheric composition via the role of photosynthesis in O₂ release and carbon burial, the carbon and nitrogen cycles, and other effects. The final and most vexing example of biosphere-atmosphere coupling is the recent influence of human industrial activity on the atmosphere, via emission of localized air pollution in cities, trace species like CFCs that alter stratospheric chemistry, and of course the long-term emissions of carbon dioxide that are currently dramatically changing our planet's climate.

Modeling of Formation, Long-Term Evolution, and Extreme Events

Techniques for modeling the formation of planetary atmospheres and their long-term evolution are usually quite distinct from the methods used to simulate present-day atmospheres. Models that span millions to billions of years of evolution generally do not have the luxury of resolving atmospheric circulation in three dimensions, so it is typical to describe the atmosphere as a vertical column or even a zero-dimensional box. Much of the challenge in producing accurate long-term atmospheric evolution models lies in accurately characterizing source and sink terms for atmospheric gases. A key source for atmospheric gases throughout a planet's history is volcanic eruptions, while a key sink is escape of the atmosphere to space. Two other processes, crustal alteration and bolide impacts, are also extremely important but can act as either sources or sinks depending on the context and gas species of interest. Data to constrain these processes comes from a variety of sources, with laboratory experiments, field observations, and geodynamic models all playing important roles. Extrapolation of processes outside of the regimes in which they are observed is frequently necessary. Stochastic (i.e., nondeterministic) modeling of atmospheric evolution is still relatively undeveloped, particularly for planets other than Earth, but is likely to grow in importance in the future.

Finally, in terms of their effect on climate and ecology, some of the most important events in atmospheric evolution are extremely short in duration and involve abrupt deviations from the mean state. Two major examples of this are

meteorite impacts and large volcanic eruptions. Both classes of event are believed to cause major short-term perturbations to the state of the atmosphere, which can have geological effects or (on inhabited planets) significantly disrupt ecosystems, giving rise to mass extinction events. Classic examples include the Chicxulub impact that triggered the demise of the non-avian dinosaurs 66 Mya, the Siberian Traps eruptions 252 Mya believed to have caused the end-Permian mass extinction, and the meteorite impacts on early Mars that have been linked to surface aqueous activity. Modeling atmosphere and climate during such events presents a challenge because of the range of physical processes involved, but some studies have tackled this difficult problem (e.g., Pierazzo et al. 2003; Steakley et al. 2019).

Key Research Findings

Terrestrial planet atmospheric modelling is such a wide research area that a comprehensive summary of findings is not possible in a single encyclopedia entry. Here, a non-exhaustive selection of some research highlights from this field is presented.

Anthropogenic Climate Change

Without any doubt, the most fundamental contribution of planetary atmosphere modelling so far in terms of societal importance has been the revelation that human emission of carbon dioxide to the atmosphere from fossil fuel burning will cause dangerous increases in Earth's global mean temperature in the future. Research since the 1900s into anthropogenic climate change has revealed with ever-increasing confidence that increases in the CO₂ abundance in Earth's atmosphere from the preindustrial level of around 280 ppmv are leading to substantial increases in surface temperature. Based on the latest ensemble results from global climate models, increases of between about 1.8 and 4 K by the end of the twenty-first century are currently predicted. The impacts of such a change on the biosphere and on human society are likely to be severe. Besides predicting changes in global mean temperature, modern climate models predict changes in climate and weather

extremes, precipitation patterns, and increasingly, the coupled effects of climate change on atmospheric chemistry, hydrology, ecosystems, and other aspects of the Earth system. Much of the remaining uncertainty in Earth climate modelling projections derives from our poor understanding of cloud feedbacks (Boucher et al. 2013).

Earth Climate History

The field of planetary climate modelling has been strongly influenced by the study of Earth's history and in some senses has grown up in parallel to it. An excellent example of this interaction is the Snowball Earth phenomenon. First hypothesized as a transition that could occur due to the ice-albedo feedback by Mikhail Budyko in 1969, Snowball Earth was initially considered to be of theoretical interest only, on the basis that if it had ever occurred, Earth would have remained forever trapped in a Snowball state. This view changed starting in 1981, when it was hypothesized that arrest of the carbonate-silicate weathering feedback in a Snowball event would lead to buildup of CO₂ in the atmosphere until the ice melted, providing an exit mechanism (Walker et al. 1981). Then, in the 1990s, mounting evidence convinced researchers that Snowball Earth episodes had in fact happened in Earth's history at least twice, in the Neoproterozoic era between 717 and 634 Ma (Kirschvink 1992; Hoffman et al. 1998). Since this time, our understanding of Snowball Earth conditions has been greatly enhanced by climate theory and modelling (Pierrehumbert et al. 2011). Snowball Earth modelling has been applied to exoplanets, where effects such as differing stellar spectrum have been investigated (Fig. 4; Joshi and Haberle 2012; Shields et al. 2013). Climate and atmospheric modelling have also been employed to elucidate many other events in Earth history, such as the Pleistocene ice ages, the rise of oxygen in the Proterozoic, and even the origin of life itself in the Hadean.

Mars Volatile Cycling, CO₂ Chemistry, and Early Evolution

One of the early successes of planetary atmospheric modelling in the space age was the deduction of the processes that govern Mars'

Modelling Terrestrial Planetary Atmospheres,
Fig. 4 Plot of the spectral energy distributions for a range of star types (top) and albedos of various surface materials for Earth-like exoplanets. Total integrated planetary albedo is a function of both the surface properties and

the star type, which leads to predicted differences in ice-albedo feedbacks and other effects for planets orbiting M-class (red dwarf) stars. (Reproduced from Shields et al. (2013))

atmospheric stability. Mars has a ~ 600 Pa atmosphere that is in quasi-steady equilibrium with surface deposits of CO_2 at the poles. Seasonal changes in insolation cause sublimation and recondensation of CO_2 ice, which leads to strong variations in atmospheric pressure. The basic features of this process were worked out in the 1960s via a combination of observations and numerical models. In the modern era, Mars climate research has focused on understanding the dust cycle on a range of spatial and temporal scales, and the water cycle, including the effect of water ice clouds on climate. Most recently, a combination of

modelling and observations has revealed strong links between the dust cycle and H_2O lofting to the high atmosphere, which enhances hydrogen escape and hence oxidation of the planet over geologic timescales (Heavens et al. 2018). Mars' early climate is also a subject of intense study because of the abundant geological evidence for liquid water in the past. Much progress has been made recently in one- and three-dimensional modelling of the early climate, although challenges remain (Wordsworth 2016).

Many insights into the photochemistry of the martian atmosphere have also been gained from

modelling. Indeed, breakthroughs in understanding of martian photochemistry preceded many developments in atmospheric chemistry on Earth. A key early question in martian photochemistry was why the atmosphere is CO₂-dominated when the photoreaction

efficiently destroys carbon dioxide, and recombination of CO and O (or O₂) is kinetically inhibited. The answer, which involves the catalytic effect of the OH radical, was first proposed in the early 1970s (McElroy and Donahue 1972). Modern models of Mars photochemistry are now able to accurately determine both bulk composition and spatial and temporal variations in key species. Challenges remain in reconciling models with observations of gases such as methane, although recent orbital observations suggest the disagreement between models and observations may be less significant than believed previously (Korablev et al. 2019).

Venus Climate and Sulfur Cycle

Early attempts to understand Venus' atmosphere and surface conditions struggled with the permanent haze layer present in the planet's upper atmosphere (a problem that is now recurring with exoplanet observations in the modern era). The surface conditions on Venus were first resolved by ground-based microwave observations, which when combined with basic reasoning and simple atmospheric models were shown to indicate high temperatures incompatible with surface liquid water (Sagan, 1961). Modern climate models are able to explain Venusian surface temperatures with fairly high accuracy, although uncertainties regarding the collision-induced absorption effect of CO₂ and the radiative role of sulfate hazes remain.

In terms of atmospheric chemistry, Venus represents a striking example of how differently a relatively familiar process on Earth (sulfate aerosol formation) can behave on a planet with similar mass but different atmospheric composition. On Earth, optically thick stratospheric H₂SO₄ hazes appear transiently in the aftermath of large

volcanic eruptions, but are not observed to last longer than a few months to a year. On Venus, in contrast, the haze layer is permanent because haze particles undergo thermolysis as they descend into the lower portions of the atmosphere. Atmospheric chemical models can now reproduce many aspects of Venusian chemistry, although several important uncertainties remain. Insights into the extreme differences in the sulfur cycle on Earth and Venus are now being used to make theoretical predictions for terrestrial exoplanets on the basis of their surface liquid water inventories (Fig. 5; Loftus et al. 2019).

Titan and the Outer Solar System

Titan is one of the great case studies for comparative planetology in our solar system. With its methane-dominated volatile cycle, low gravity, and thick atmosphere, it exhibits strangely Earth-like behavior in some respects, but is in other ways a radically different world. As is so often the case in planetary science, our understanding of Titan's atmosphere has been driven by spacecraft observations, of which the Voyager 1 and Cassini-Huygens missions were particularly important. Notable modelling advances enabled by these observations include a theoretical explanation of the *anti-greenhouse* nature of Titan's tholin haze (McKay et al. 1989), development of vertically resolved photochemical models of the planet's atmosphere (Yung and DeMore 1998), and a greater understanding of the unusual properties of methane rain microphysics (Lorenz 1993). Although our understanding of Titan has grown immensely over the last few decades, many uncertainties about its atmospheric processes and long-term evolution remain. Finally, atmospheric modelling of other outer solar system objects, such as Pluto, is still in the early stages of development but has nonetheless already shown success in explaining key observations by spacecraft such as New Horizons (Fig. 6; Bertrand and Forget 2016).

Terrestrial Exoplanets

Given the scarcity of observations of terrestrial exoplanet atmospheres in 2020, it would be premature to claim that atmospheric modelling

Modelling Terrestrial Planetary Atmospheres, Fig. 5

Simulated likelihood of the buildup of a permanent sulfate aerosol haze layer on Earth-like exoplanets with variable ocean volumes and pH levels, based on the results of an idealized sulfur cycle model. Results show that upper atmospheric observations of an exoplanet may be used to constrain the presence/absence of surface liquid water indirectly. (Reproduced from Loftus et al. (2019))

(or more accurately, the combination of observations and modelling) has yet led to major advances. Nonetheless, initial steps have already been made in this exciting new direction. For most discovered exoplanets in the terrestrial mass regime, the information we have available is radius, orbital distance, and in some cases, planet mass. A small subset of these planets are amenable to follow-up observations via transit spectroscopy, and for a few of them, constraints on atmospheric properties are now emerging (Diamond-Lowe et al. 2018; Kreidberg et al. 2019).

Considerable attention has been paid recently to the physical processes that drive the loss of molecular hydrogen from terrestrial-type planetary atmospheres. It is now clear that the division between gas/ice giants and rocky planets in the solar system is unusually distinct, and an emerging class of “enveloped terrestrial planets” appear to have both predominately rocky composition and hydrogen-dominated atmospheres. How the transition from enveloped terrestrial planets to rocky worlds like those in our solar system occurs is still a subject of investigation, with photo-evaporative and “core-powered” hydrogen loss to space currently among the leading hypotheses.

Most terrestrial planets with observable atmospheres will be around M-class (red dwarf) stars, rather than Sun-like stars, for the near to medium term future. As a result, much modelling work has focused on the differences in evolution that should occur for planets in M-class systems. Early work noted that planets that receive Earth-like levels of stellar irradiation will have close orbits around M-stars and hence may be tidally resonant or completely locked, with permanent day and night sides. General circulation modelling work has established that thin atmospheres may freeze out on the night side in this case, but thicker (i.e., greater than about 0.1 bar) atmospheres can remain stable. Notably, analytical formulae can successfully predict the day-night temperature differences on such planets obtained in far more complicated general circulation models, which is interesting given how difficult it is to create quantitative models of heat redistribution on planets like Earth. Other recent theoretical results of note

for M-dwarf terrestrial planets include predictions of enhanced cooling due to higher reflectivity from thicker clouds on the planet’s permanent dayside (Yang et al. 2013), predictions of water loss and abiotic O₂ buildup as a result of the long pre-main sequence phase that M-stars undergo (Luger and Barnes 2015; Schaefer et al. 2016), and predictions of high rates of atmospheric erosion generally due to enhanced stellar activity. All of these predictions are going to be testable in the coming decades when next ground and space-based observing facilities come online, but for the moment they remain unproven by observational data.

Applications

The applications of terrestrial planet atmosphere models are as diverse as the planets themselves. On Earth, atmosphere modelling contributes in a fundamental way to environmental science, operational meteorology, and to predictions of the impacts of climate change on global to regional scales. On longer timescales, atmospheric modelling informs us of paleoclimate conditions in the recent and distant past, with implications for archaeology, geochemistry, paleontology, and geobiology, to name just a few disciplines.

On solar system planets, there are already some operational applications for atmospheric modelling, most notably on Mars where global circulation model predictions are used to assess landing site risks for rover missions. As exploration of the solar system continues, these applications will grow accordingly. More broadly, atmospheric models of solar system planets allow big picture questions in planetary science to be addressed. For example, on Titan, the puzzle of the high atmospheric methane content requires coupling of atmospheric models to models of the deep interior. On Mars, climate modelling is needed to provide context to geological observations, and the search for life is strongly influenced by our evolving understanding of the planet’s early climate. On Venus, questions about the long-term stability of the atmosphere drive improvements in our understanding of processes like high-

temperature mineralogy at the surface and volcanism at high temperature and pressure. For early Venus, climate modelling is also needed to identify whether a *runaway greenhouse* phenomenon ever occurred (and if so at what point in the planet's history).

Finally, for exoplanets, atmospheric science is particularly critical because for the majority of cases, the atmosphere is the only part of the planet we are ever able to view directly. For the planets with atmospheres that can be observed today (which are not capable of supporting Earth-like life), atmospheric modelling allows competing theories of evolution to be tested and the maximum information to be gained from sparse observations. For potentially inhabited exoplanets, the importance of atmospheric modelling is even greater. Life detection relies on the concept of an atmospheric "biosignature," which is meant to be an observation that is a unique determinant of life. Identifying biosignature gases is an ongoing challenge that is addressed through a combination of atmospheric evolution and chemical modelling. This work is important for identifying *false positive* biosignature gases (or gas combinations), such as O_2 in cases where photochemical dissociation of H_2O and subsequent loss to space of hydrogen is effective.

Future Directions

Advances in terrestrial planet atmosphere modelling in the future are likely to occur primarily through close intercomparison between model results and observations. Despite decades of improvements to models and many demonstrations of their descriptive and predictive power on Earth and other planets, clear challenges remain. From a climate perspective, clouds remain a major source of uncertainty in predictions of anthropogenic climate change, of paleoclimate on Earth and Mars, and of the habitability of exoplanets. Reduction in model uncertainty will require a combination of more physically grounded models of convection and cloud microphysics, a better understanding of cloud radiative transfer, and in some cases further increases in model resolution and complexity. Finally, for many areas of atmospheric modelling,

better constraints on basic processes from either laboratory experiments or fundamental physics/chemistry calculations are still required.

Major outstanding questions remain regarding the long-term evolution of Venus, Mars, and Titan. For Venus, it is still unclear whether surface liquid water was ever present, and if so for how long. For Mars, the evidence for ancient surface liquid water is incontrovertible, but explaining how it occurred is still a major climate modelling problem. For Titan, the apparent instability of its current atmosphere to methane photodissociation and hydrogen loss to space raises major questions about the evolution of its atmosphere through time and effect of interior processes on a world that has no analogue in the inner solar system. For all solar system objects, more data from spacecraft missions is required to continue providing vital constraints that allow models to be tested.

The emerging field of exoplanets provides both challenges and immense opportunities. Exoplanet observations will provide data on a huge range of targets. Although this data will be very limited compared to what we have available in the solar system, the fact that it will cover such a wide range of planets means that it will revolutionize our understanding of many planetary processes. Within the next decade, it is likely that long-standing questions from solar system planetary science will be elucidated by exoplanet observations and modelling. For terrestrial-type targets, the best information will initially come from planets too hot to support life. Ultimately, however, high quality observations of potentially habitable exoplanets will become possible, and modelling of terrestrial-type atmospheres will be able to contribute to the grand challenge of searching for life in other star systems.

Moiety

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

In organic chemistry, the term moiety is used to denote a portion of a molecule, which may be a

functional group, or to describe a portion of a molecule with multiple functional groups which share common structural aspects. For example, the molecule NAD^+ (nicotinamide adenine dinucleotide) contains nicotinamide, which includes an amide functional group, in which the amide functional group can be described as containing both amine and carboxylic moieties, in this case ammonia and nicotinic acid, respectively. The two terms (moiety and functional group) are often used synonymously; however, the International Union of Pure and Applied Chemistry (IUPAC) makes a distinction between the two, although in common practice this distinction can be ambiguous. Nevertheless, “functional group” is generally reserved for a portion of a molecule with some common chemical behavior, while “moiety” is more often used as a structural description.

Mole

John H. Chalmers
Scripps Institute of Oceanography Geosciences
Research Division, University of California, San
Diego, CA, USA

Definition

A mole is the amount of matter consisting of one Avogadro's number ($\sim 6.022 \times 10^{23}$) of atoms, molecules, or elementary particles. Operationally, a mole is the atomic, molecular, or formula weight expressed in grams, but this usage is obsolete, and one should use relative atomic mass or relative molecular mass in kilograms multiplied by 10^{-3} according to rules of the International System of Units (SI).

Synonyms

[Molecular beacon probe](#)

Definition

In molecular biology, molecular beacons are ► [oligonucleotide](#) ► [hybridization](#) probes used to report the presence of specific nucleic acids in heterogeneous solutions. They are hairpin-shaped molecules with an internally quenched ► [fluorophore](#) whose ► [fluorescence](#) is restored when they bind to a target nucleic acid sequence. This is a method of detecting specific nucleic acid sequences. They are useful when it is either not possible or desirable to isolate the target nucleic acid sequence from an excess of the hybridization probes. They are typically ~ 25 nucleotides long. The middle 15–30 nucleotides are complementary to the target sequence, and the five nucleotides at each end are complementary to each other and not to the target DNA. At the 5' end of the beacon a fluorophore is attached, and at the 3' end a quencher is attached. When the molecule is not hybridized to the target sequence, fluorescence quenching occurs. After hybridization quenching is stopped, the fluorophore is able to emit light.

Molecular Beams

Nadia Balucani

Dipartimento di Chimica, Biologia e
Biotecnologie, Università degli Studi di Perugia,
Perugia, Italy

Acronyms

[MB]

Definition

Molecular beams are streams of molecules (or, in a broader sense, other particles such as atoms, free radicals, ions) that move in the same direction and with a defined speed range. They are produced by expanding a gas from a high-pressure region to a low-pressure region through an orifice. According to the way in which the expansion is obtained, they can be distinguished into effusive or supersonic beams. Also, they can be continuous or pulsed if a pulsed valve is used instead of an open orifice. Molecular beams can be used to investigate chemical reactions in crossed molecular beam experiments.

History

Since their development, molecular beams have been used in many different research fields. In the context of astrochemistry and astrobiology, the role of molecular beams is related to the study of elementary chemical reactions in the gaseous phase and, in particular, of bimolecular reactions between neutral species (although several studies for ion-molecule reactions are available in the literature). This technique, coupled with

spectroscopic methods or mass spectrometry, allows one to measure reactive cross sections, determine the nature of the reaction products and their yield, study the reaction dynamics and establish the mechanism followed by the process. Reactive processes are studied under single collision conditions, thus reproducing the low number density conditions for the reactions that occur in the interstellar medium, in cometary comae and in the rarefied regions of planetary atmospheres. In this way, the formation route of the organic molecules, with prebiotic potential, that have been identified in those environments can be clarified and their possible role in the origin of life speculated.

Neutral theory of evolution · Time ·
Evolutionary rate · Fossil record · Calibration

Definition

The molecular clock is a technique used to estimate divergence times in a phylogeny using calibrations, generally from the fossil record, and evolutionary rates. Its theoretical background is rooted in the neutral theory of evolution which predicts the approximately linear accumulation of neutral substitutions in genes through time. Molecular clocks use sequence alignments of nucleotides or amino acids to estimate the time of speciation events and the evolution of gene families by duplication. They are the basis for the estimation of the time tree of life, which is a chronological depiction of the origin of major taxonomic groups throughout Earth's history.

Overview

Molecular clocks provide a powerful tool used to estimate the chronological dimension of a phylogeny where nodes can represent speciation or duplication events. Their theory rests on the observation that genetically similar sequences (of either nucleotides or amino acids) share a more recent common ancestor compared to sequences that are more different. In other words, neutral substitutions (i.e., neutral

mutations in nucleotide or amino acid states between pairs of sequences) stochastically accumulate through time in an approximately linear fashion (Zuckerandl and Pauling 1962; Kimura 1968).

According to this hypothesis, the divergence time of a node can be obtained by the relation $t = d/r$, where t is time, d is the genetic distance for a pair of sequences, and r is the rate of accumulation of substitutions. Because the rate parameter is expressed in time units (e.g., number of nucleotide/amino acid substitutions per million years), it is necessary to provide time information for at least one node in the phylogeny in the form of a calibration point. This node generally marks a speciation event recorded in the fossil record which can be used to estimate an approximate rate of substitution. Such a rate can then be used to extrapolate the time of divergence of other nodes in the phylogeny which will all be scaled to the same time unit provided by the calibration (e.g., millions of years).

Basic Methodology

Molecular clocks fall into one of two main categories based on their treatment of substitution rates. Initial methods, called global clocks, assumed a single substitution rate for all branches in the tree, a condition that seemed plausible given the initially small datasets available. However, the availability of larger numbers of molecular sequences, in terms of species and genes, showed the fallacy of this assumption: genes evolve at different substitution rates, and some lineages evolve faster than others. Corrective measures to address the issue of rate variation led to the development of molecular clock approaches that take into consideration rate variation among branches. The linearized tree method (Takezaki et al. 1995) takes advantage of relative rate tests to identify those genes and lineages violating the rate constancy assumption and removes them from the dataset. This method reduces the size of the dataset in order to preserve the validity of the rate constancy assumption of global clocks. Alternative methods, such as local and relaxed clocks,

allow for various degrees of flexibility in rate variation among branches permitting the analysis of larger datasets irrespective of their evolutionary complexity. While the local clocks require an *a priori* identification of groups of branches evolving at different rates, relaxed clocks, which are the most commonly used methods, estimate substitution rates specific to each branch in the phylogeny (Kumar 2005).

The correct modeling of rates is also highly dependent on the calibration point(s) used to scale the genetic distances to time units. These points are nodes in the tree for which independent information regarding their time is available from nonmolecular data. For example, in a phylogeny of multiple species, the fossil record can often be used to anchor some of the nodes to the time of the geologic stratum in which the fossils for a given lineage are found. Unfortunately, few well-constrained calibration nodes are available to time large phylogenies and, in most cases, are constrained to the Phanerozoic. The limitation of the fossil record results in higher uncertainties for more ancient divergence times because the estimated nodes are farther removed from the available calibrations.

In relaxed clock methods, the final step of time estimation for each node in the phylogeny is the result of a maximum-likelihood (ML) or Bayesian approach that uses the calculated genetic distances and evolutionary rates to provide an optimized timeline of the phylogeny under study. The use of these heuristic methods is necessary for the estimation of divergence times in large phylogenies that present a parameter space that is too large to be exhaustively explored. In order to restrict the plausible parameter space, ML and Bayesian methods require the specification of a set of *a priori* parameters that provide a plausible starting point for the search algorithm. In most cases, these priors are unknown, and default values are used without a clear understanding of the effects on the accuracy of estimations. For this reason, recent efforts have been directed toward the development of molecular clocks that require only few prior parameters (Tamura et al. 2012).

The accuracy of molecular clock analyses can be affected by a number of methodological

problems that are being actively investigated. Among these, two are prominent: the model of rate variation and the use of calibration points. Although relaxed clocks allow for rate changes to happen on each branch, most methods (e.g., BEAST, MCMCTree, Phylobayes) require a model of rate changes among branches that will be used as a basis to estimate the actual branch-specific substitution rate (Drummond and Rambaut 2007; Dos Reis and Yang 2011; Lartillot et al. 2009). Currently, two models are being used: the autocorrelated and the uncorrelated models. The first assumes small rate changes between ancestor and descendant lineages and is justified by biological similarities of closely related species. The second, instead, does not constrain the amount of rate variation change between branches, based on the assumption that missing lineages in a phylogeny may be hiding the gradual nature of the process of substitution accumulation, especially for distantly related lineages. Simulation studies have shown that time estimates based on these two models can be different, thus raising the issue of how to choose the most appropriate model when *a priori* information is not available.

The other issue known to affect the accuracy of the estimated times is the use of calibration points. This issue is twofold: first, the number of calibration points is usually small compared to the total number of nodes in a phylogeny. This means that many of the nodes to be estimated will be phylogenetically distant from the calibration used. Extrapolation of rates and correlated divergence times becomes increasingly uncertain with larger distance from the calibration because of error propagation in estimates from branch to branch. There is therefore great interest in increasing the number of calibrations. Unfortunately, this is difficult to achieve because of the incompleteness of the fossil record and the uncertainty surrounding many potential calibration points. Simulation and empirical studies have shown that the use of few well-constrained calibration points produces time estimates that are more accurate than those obtained using more numerous but less accurate calibrations (Hedges and Kumar 2004; Graur and Martin 2004).

Second, the boundaries used to define the calibrations are often uncertain. Calibration points can be defined using three types of boundaries: (i) a minimum-only boundary that allows the node to be potentially older, but not younger, than the given value; (ii) a maximum-only boundary which is the opposite of the minimum boundary; and (iii) a combination of minimum-maximum boundaries that constrains the node in both temporal directions. Furthermore, each of these types can be associated with a different probability distribution that is a measure of the confidence in the value provided. For example, a lognormal distribution on a minimum-only boundary can have a very long left tail (extending toward deeper times) in those cases in which we suspect the node in question to be much older than its fossil record. Unfortunately, boundaries and probability distribution are, in many cases, subjective, and their different use can lead to discrepancies in molecular clock analyses.

Key Research Findings

For centuries, the fossil record was the only source of information on the past evolution of species. However, this record is applicable, almost exclusively, to macroscopic species and, even for many of these, is incomplete. Moreover, the majority of the tree of life is composed of microbes (prokaryotes and unicellular eukaryotes) for which little or no chronological information can be obtained from nonmolecular data. One of the major findings of molecular clocks has been a timeline of life from the first prokaryote divergences in the Archean eon to the recent evolution of pathogenic strains of bacteria and viruses (Hedges and Kumar 2009). The time tree of life provides insights into the evolution of Earth as a habitable planet highlighting the correlation between the coevolution of major metabolisms and the changes in Earth's geosphere. The most classic example of this is the connection between the evolution of cyanobacteria, their oxygenic photosynthesizing metabolism, and the rise in atmospheric oxygen levels ~2.4 billion years ago (Holland 2002). In addition to producing a

time tree of species, molecular clocks are the only approach able to estimate the time of evolution of genes and gene families. This approach is fundamental to uncover the connections between genetic innovations, phenotypic variability, and environmental effects.

Applications

Applications of molecular clocks span many fields in evolutionary biology, from the chronology of species divergences to the origin of genes and gene families. The most recent application is within the field of evolutionary medicine in which molecular clocks are being used to identify the genetic origins of diseases in humans.

Future Directions

The application of molecular clocks to the evolution of genes and gene families is still in its infancy and requires a systematic evaluation of its accuracy. Nonetheless, this approach holds great potential in uncovering coevolutionary mechanisms between genotypes and environmental changes. Knowledge of such mechanisms will be necessary to understand not only the evolution of life in the history of Earth but also life's potential response to future planetary-scale environmental changes and its eventual interactions with extraterrestrial environments.

Molecular Cloud

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Definition

A molecular cloud is a concentration of interstellar gas and dust in which the gas phase is primarily molecular, with the dominant constituent being molecular hydrogen (H₂). It is in molecular clouds that new stars and planetary systems are born. Because molecular hydrogen lacks pure rotational transitions, molecular clouds are normally traced

by radio astronomers by observing the millimeter-wavelength transitions of the next most abundant constituent, carbon monoxide (CO). There are in addition more than 150 other molecular species that have been detected in molecular clouds, most of these species being organic (see ► [Molecules in Space](#)). Although molecular clouds occupy only a small fraction of the volume of the Milky Way and other galaxies, they contain a significant fraction of the total gas mass. The largest such clouds are called giant molecular clouds, or GMCs, and can contain more than a million times the mass of the Sun. For a comprehensive description of the ► [Interstellar Medium](#), see the entry in this Encyclopedia.

Definition

Molecular fossils are organic molecules derived from once living organisms. They fall within the category of biomarkers (or biosignatures), which are substances or characteristics that indicate a modern or past biological presence, state, or process. Molecular fossils are definitive biosignatures, and most of them are unambiguously derived cell ► [membrane](#) lipids and other aliphatic ► [hydrocarbons](#). Structures and abundances of molecular fossils and their precursor biomarkers show varying degrees of biological and environmental specificity, which reflect genetic, enzymatic, and environmentally controlled lipid production by source organisms (Gaines et al. 2009; Eglinton and Pancost 2004). Molecular fossil structures also record the nature and extent of some diagenetic and postdepositional geological conditions, and

their isotopic compositions record metabolic and environmental information.

History

The first molecular fossils were discovered in the 1930s by Alfred Treibs who observed porphyrins (compounds derived from chlorophylls a or b) in ancient oil, shale, and coal (Kvenvolden 2002). In the 1960s Geoffrey Eglinton and colleagues proposed the concept of molecular fossils as recorders to ancient microbial life. By the early 1970s it was well established that petroleum was composed of molecules of ancient biological origin and contained molecular fossils. Subsequent petroleum and paleoenvironmental research provided a foundation for understanding the occurrences, modifications, and environmental relationships of molecular fossils in the geological record. By the 1990s, organic biogeochemical studies (structural and isotopic) of recent sediments and modern environments provided the crucial observations required to ground the molecular fossil approach to the geobiological record (e.g., Freeman et al. 1990; Hayes et al. 1990; Logan et al. 1995; Summons and Jahnke 1992; Summons et al. 1987).

Overview

When organisms die, their cells decompose. Most biomolecules released to the ambient environment are oxidized or reworked by living microbes and geochemicals. However, in some aqueous environments, biomolecules are preserved by reaction, sorption, and encapsulation by minerals or more refractory organic carbon. Under anoxic conditions, they may also react with sulfur to produce sulfurized molecules or may form kerogen-like macromolecules that aid their preservation. Most biomolecules are highly functional and thus quite labile in oxidizing or nutrient-limited environments. In contrast, membrane lipids are mostly composed of a hydrocarbon skeleton, which makes them more refractory. Over geological time scales (10^4 – 10^6 years), lipids lose any weakly bound head groups and are defunctionalized

(e.g., loss of double bonds or carboxyl, hydroxyl, and amino groups) and reduced. This leaves the hydrocarbon skeleton relatively unaltered for preservation in rocks as constituents of ► **kerogen**, bitumen, oil, resins, or coal. For example, fatty acid lipids may preserve as esters or alkanes, β -carotene as carotane, cholesterol as cholestane, and bacteriohopanepolyol lipids as hopanes (Fig. 1). Importantly, lipids are released to the environment in high abundance, especially by microorganisms, but only a small amount is actually preserved. What is more, lipids have varying functionality, three-dimensional shapes, and biomineral associations that may lead to preferential preservation under certain circumstances. It is during early diagenesis that the fate of most biomolecules in sediments is determined. In general, the faster biomolecules are buried and removed from oxidizing conditions, the greater their potential is for preservation as molecular fossils in the geological record (see Eigenbrode 2007 for review).

A variety of molecular fossils in geological records are observed, and they have identifiable lipid precursors in living organisms. The organic geochemical record reflects a dominance of microbial molecular fossils, which is extremely valuable since unambiguous macrofossil of microorganisms is rare and microorganisms have played a key role in biogeochemical cycling over 3.5 billion years of Earth's history. These fossils include, but are not limited to, acyclic ► **isoprenoids**; aryl isoprenoids; bi-, tri-, and tetracyclic terpenoids; and pentacyclic terpenoids including hopanoids, oleanoids, and steroids. Other hydrocarbon structures (e.g., *n*-alkanes, alkyl-alkanes, organic acids, and polyaromatic hydrocarbons) may be regarded as potential biosignatures and hence not necessarily molecular fossils, since they may form from abiogenic processes. Molecular patterns in their structures and isotopic composition may help ascertain whether these compounds are indeed molecular fossils.

As membrane biomolecules, the evolution of lipids is highly conserved due to their key role in providing the necessary membrane rigidity and selective permeability required by organisms that need to separate cellular chemistry from the ambient environment while still passing selective

substrates and waste product through membranes. Cell membranes are similar to nonbiologically formed liposomes, where, in the presence of water, polar head groups of molecules having hydrocarbon tails, such as carboxylic acids with carbon chains, line up to form a polar (or hydrophilic) surface facing the water. The hydrocarbon tails make up a hydrophobic region that repels water, thus creating a structural boundary for isolating different chemical environments. Most biological cell membranes are composed of two layers with hydrocarbon tails facing the center of the bilayer. Life has evolved hydrocarbon structures that are much more complex than simple straight chains of carbon. Branches, cyclic rings, double bonds, and, sometimes, alcohol groups are included in the hydrocarbon tail and consequently change the functionality of the lipid and the characteristics of the membrane. In addition, the hydrocarbon tail may be linked to a wide diversity of polar head groups by ester bonds or ether bonds, as is diagnostic of the domain ► **Archaea** membranes. The fundamental need for all cellular life to maintain membranes limits the structural possibilities for lipids, thus explaining the occurrence of common molecular fossil groups throughout the geological record.

The provenance of different molecular fossils and their lipid precursors has largely been established through a combination of studies including lipid compositions associated with particular modern organisms or environmental conditions, molecular fossils associated with past environmental settings or diagenetic conditions, an understanding of the biochemical pathway for synthesizing lipids, and, more recently, phylogenetic analyses targeting the presence or absence of genes required for making the key enzymes of these pathways. These efforts are being pushed further by the application of molecular clock approaches to elucidate when in Earth's history different groups and biosynthetic pathways have evolved. Establishing biological provenance of lipid structures and their molecular fossils is a very active research field. However, there is consensus on the conservation of key lipid assemblages along major evolutionary lines. These key assemblages include hopanoids, acyclic

Molecular Fossils, Fig. 1 Geological alteration of cellular membrane lipids to molecular fossils: (a) bacteriohopanetetrol glycoside to pentakishomohopane, (b) cholesterol

to cholestane, (c) β -carotene to β -carotane, and (d) cardarchaeol to biphytane

isoprenoid alcohols and ethers, and steroids (particularly those having an alkyl group at the C24 position) that are diagnostic of the ► *Bacteria*, Archaea, and ► *Eukarya* domains (Fig. 2). Other lipids and their molecular fossils show varying degrees of taxonomic and environmental specificity. Examples of strong taxonomic associations include certain aryl isoprenoids diagnostic energy-harvesting biomolecules (carotenoids) of green sulfur bacteria, 2-methyl hopanoids common of cyanobacteria and some α -proteobacteria (Welander et al. 2010), and 3-methyl hopanoids diagnostic of type I aerobic methylotrophic bacteria. Examples of environmental associations are aryl isoprenoids diagnostic of euxinic photic zones and 2-methyl hopanoids of marine carbonate environments. Often, where individual compound specificity falls short, assemblage analyses may be utilized to elucidate biologic origin. Taxonomic and/or environmental provenances can be used to infer past depositional or diagenetic conditions and biological community composition;

thus, molecular fossils can be extremely useful in furthering our understanding of the evolution Earth's biosphere.

Applications of molecular fossils can be hampered by poor preservation, loss (destruction or migration out of the rock), and overprinting by later processes. Factors that influence establishment and detection of a molecular fossil record may impact the initial preservation, long-term preservation, or sampling and analysis. Even though lipids are more recalcitrant to biological and geochemical oxidation, they are still susceptible to this form of destruction, particularly if they are exposed to water, gas, and chemical exchange or geothermal heat over geological time. For this reason, sediments of high permeability (e.g., sandstones) are not likely to preserve indigenous molecular fossils. In contrast, low-permeability sediments, such as mudstone and shale, boost the likelihood of preservation. Anoxic environments are more favorable for initial preservation. Sediment compositions that help

to stabilize the redox conditions during burial, even if in microcavities of pores or mineral inclusions, will improve the preservation potential. Furthermore, it is a natural consequence of burial and geological activities for sedimentary organic matter containing molecular fossils to undergo thermal maturation. As part of early diagenesis, many biomolecules chemically react with each other, minerals, and solutes (e.g., phyllosilicates or sulfides) to form sedimentary macromolecules, while some biomolecules maintain their original macromolecular form. In rocks, this macromolecular material is called kerogen. Formation of macromolecules aids the preservation of molecular fossil constituents contained within them. Following diagenesis, heat thermally matures organic matter through a process known as catagenesis. The weaker bonds holding the macromolecules together are thermally broken resulting in the release of molecular fossils and overall loss of O, S, N, and eventually H. The molecules freed from the kerogen may be retained by the host rock as bitumen or migrate to other rocks as oil. Decades of petroleum research have demonstrated that bulk characteristics of bitumen and oil, as well as composition of the thermally matured molecular fossil record aspects of these alteration processes often without complete loss of structural information diagnostic of biological and environmental provenance. Moreover, owing to a ubiquitous biosphere, the molecular fossil record is continually susceptible to alteration by biology in the subsurface (particularly carried by groundwater) and surface once rocks are reexposed. The extent that the original syngenetic record of the host rocks is lost or overprinted by lipids from newly introduced biology will largely depend on the level of metabolic activity, biomass turnover, and time. As with thermal maturation, there are chemical signatures that record the biological alteration. Lastly, the same factors that influence preservation in the rock record apply to sampling, storage, and analysis. Once a sample is removed from its *in situ* conditions, it is susceptible to oxidation, contamination, and other degradations. These factors become increasingly important for the recovery of trace quantities (sub-ppb concentrations) of indigenous molecular fossils.

Thus, under favorable conditions, carbon skeletons of lipids have the potential to be preserved as molecular fossils for billions of years, but their detection and recognition as indigenous and syngenetic signatures of host rocks may be dependent on resolving the complex record of alteration occurring since deposition.

Basic Methodology

Molecular biomarkers and their fossils are typically recovered from biological materials, sediments, oil, bitumen in rocks, or coal using organic solvents. The molecular composition (structures, molecular abundances, and compound-specific isotopic compositions) is then determined using highly sensitive analytical tools such as gas or liquid chromatographs and mass spectrometers. Alternative extraction approaches involve laser desorption ionization (e.g., LDI and MALDI), extraction by heat instead of solvents (e.g., thermal desorption and pyrolysis) or some combination of heat, chemical reactants, and solvents (e.g., thermochemolysis).

Key Research Findings

The field of molecular fossil research has been evolving for over 50 years. Some of the more recent key research findings include, but are not limited to, the following:

1. The finding that preservation of molecular fossil record occurs largely through abiotic reductive transformation by the early diagenetic incorporation of sulfur into sedimentary lipids and other biomolecules (Hebting et al. 2006; Adam et al. 1993; Sinninghe Damsté et al. 1989).
2. The analytical advancement of compound-specific isotope analysis (CSIA) via gas chromatography–isotope ratio mass spectrometry (GC-IRMS) and the recognition that molecular fossils (and their lipid precursors) retain isotopic signatures diagnostic of carbon sources and metabolisms (Freeman et al. 1990; Hayes et al. 1990; Pancost and Sinninghe Damsté 2003). This finding opened a new door to

- understanding the activities of community organisms in past environments and has expanded to include CSIA of nitrogen, hydrogen, and sulfur. More recently, this has been expanded to site-specific isotopic measurements as well as analysis of clumped isotopes.
3. Taxonomic, metabolic, and environmental interpretations of molecular fossils are largely dependent on their observed occurrence in the sedimentary rocks and modern biota. More recently, however, new insights in the molecular fossil sources are coming from the application of genomic techniques to evaluate lipid biosynthetic capabilities (Welander et al. 2010; Fischer et al. 2005; Pearson et al. 2003) and lipid function (Welander et al. 2009).
 4. Observations and subsequent critical analyses of a suite of originally proposed indigenous and syngenetic molecular fossils of Neoproterozoic sediments that are indicative of ancient microbial diversity (Brocks et al. 1999; Waldbauer et al. 2009; French et al. 2015) and changes in biological oxygen and methane use (Eigenbrode et al. 2008) beginning >200 million years before the first significant rise in atmospheric oxygen concentrations at 2.5 Ga. However, the antiquity of these biomarkers is subject to debate and contamination suspected for most of the Archean record (Rasmussen et al. 2008; French et al. 2013).
 5. The discovery of the steroid, 24-isopropylcholestane, a molecular fossil of demosponges, Neoproterozoic Maronian glacial cap carbonate rocks, pushes back the record of animals on Earth to 635 Ma, making it the oldest evidence for animals (Love et al. 2009), though this also has undergone additional scrutiny recently as the diagnostic compound has also been reported from an alternative source (Nettersheim et al. 2019).
- community composition, and ecologies – all of which are useful in paleoclimate studies (e.g., Zachos et al. 2006), constraining biological evolution (e.g., Brocks et al. 1999; Love et al. 2009), understanding catastrophic and global events (e.g., Grice et al. 2005; Eigenbrode et al. 2008), and correlating oil source rocks with petroleum reservoirs (cf. Peters et al. 2007). Molecular fossils are particularly useful as markers for microbial contributions to sediments (cf. Brocks and Summons 2003), and their isotopic compositions can reveal associated metabolisms and biogeochemical cycling (e.g., Freeman et al. 1990; Pancost and Sinningh-Damsté 2003).
- In extraterrestrial studies, the identification of molecular fossils as definitive biosignatures will be a particularly difficult challenge in the absence of a broad understanding of the biochemistry, physiology, and ecology of modern extraterrestrial life. However, molecular biomarker and molecular fossil studies on Earth reveal generic traits of life (Summons et al. 2007) and ecology (Eigenbrode 2007) that will be essential in evaluating the biosignature potential of extraterrestrial organic molecules. Moreover, organic geochemical studies provide the foundation for understanding sources (biogenic or abiogenic) as well as surface and subsurface alteration processes. A caveat to extraterrestrial studies will be confirmation that the molecules detected are indigenous and were not transported from Earth.

Future Directions

Contemporary interdisciplinary studies that integrate lipid biomarkers, isotopic compositions, microbial physiology and ecology, and microbial genomics are advancing our understanding of molecular biomarker specificity for phylogenetic groups and environmental conditions. Concurrent research efforts that focus on the fate of molecular biomarkers from origin to deposition and preservation in the geological record are providing essential insight for detecting and improving the recovery of molecular fossil records. Both lines of study aim to revolutionize our understanding of

Applications

On Earth, molecular fossils are used to understand a variety of aspects about ancient life (cf. Gaines et al. 2009). They are particularly valuable in reconstructing ancient environmental conditions,

evolution of the biosphere on Earth and will aid in the exploration, detection, and establishment of biogenetic confirmation criteria for molecular biomarkers and their fossils in extraterrestrial sediments should they exist.

Keywords

Interstellar medium · Molecules

Definition

Molecular line cooling is the physical process whereby de-excitation of collisionally or radiatively excited molecules leads to the emission of a photon, followed by the photon's escape from the local cloud volume, thus cooling the local gas.

Overview

In astronomical environments where most of the gas is molecular, the gas can cool through emission of the photons associated with transitions from higher to lower rotational and vibrational levels in molecules. In cold ► [molecular clouds](#), the major molecular coolant is CO, since the most abundant constituent (H₂) lacks radiative transitions at low temperatures. In shock waves, H₂, H₂O, and CO dominate the molecular cooling. Other molecules that can act as relatively minor coolants are OH, HD, and CH. In ► [photodissociation regions](#), atomic fine structure lines can also be important coolants.

Definition

A molecular line map is a spatial representation of molecular line emission from an extended astronomical source. Such maps are normally represented in the astronomical coordinates ► [Right Ascension](#) and ► [Declination](#) or in off-sets from a defined position on the sky. Molecular lines are observed either on a predefined set of grid points or by continuous scanning (On-The-Fly mapping), and a map is constructed from the emission intensity, either as contours or using gray or color scales.

Definition

A molecular line survey is a study of the spectrum of an astronomical source over a wide, approximately continuous, range of wavelengths, in order to determine the chemical composition and physical properties (temperature, density, and internal motion) of such a region. Primarily, the lower energy transitions of molecules of astrophysical interest are excited at the cold temperatures of ► [molecular clouds](#), and these rotational transitions are typically at centimeter and (sub)millimeter wavelengths (~10–1000 GHz), so that molecular line surveys have normally been carried out using the techniques of radio astronomy.

History

Until recently, radio receivers had instantaneous spectral bandwidths that covered only very small

fractions of the wavelength regions of interest. Consequently, searches for and studies of interstellar molecules were traditionally targeted toward the narrow regions around laboratory-measured transition frequencies of specific molecules. In contrast, spectral line surveys were very time-consuming and could only be carried out at those radio observatories that were willing to devote significant observing time to a survey project. The first spectral line survey was made during 1977–1982 toward the giant molecular cloud known as Sagittarius B2 (Sgr B2) near the center of the Milky Way Galaxy (Cummins et al. 1986), using an antenna at the Bell Laboratories, USA.

The first major projects with the new 20-m-diameter radio telescope at the Onsala Space Observatory in Sweden were line surveys of the nearest region of massive star formation to the Sun, Orion-KL, and the envelope expelled by the evolved carbon star, IRC +10,216 (Johansson et al. 1984). This survey found striking chemical heterogeneity within the Orion molecular cloud. These studies were extended to both higher and lower frequencies in subsequent surveys (e.g., Blake et al. 1987; Turner 1991; Nummelin et al. 1998; Cernicharo et al. 2000; Kawaguchi et al. 1995; Ziurys and McGonagle 1993; Lee et al. 2001) and to additional sources in our Galaxy (e.g., Fontani et al. 2017; Kaifu et al. 2004; Pardo et al. 2007; Helmich and van Dishoeck 1997; Macdonald et al. 1996; van Dishoeck et al. 1995).

The Orion molecular cloud has been surveyed at frequencies blocked by the Earth's atmosphere, using the Odin satellite (Olofsson et al. 2007), and spectral line surveys have been extended to external galaxies (Martin et al. 2006). Surveys of the Orion molecular cloud and Sgr B2(N) have been extended to cm wavelengths with the Green Bank Telescope (GBT) (see, e.g., McGuire et al. 2012) and to THz frequencies with the Herschel Space Observatory (HSO) (Neill et al. 2012). Finally, the Atacama Large Millimeter Array (► ALMA) has sufficient spectral bandwidth and resolution to conduct broadband line surveys commensurate with spatial mapping (e.g., Belloche et al. 2016; Pagani et al. 2019).

Overview

There are many specific reasons why deep spectral line surveys are important and timely, and could significantly advance the field of astrobiology. Surveys not only provide probes of physical and chemical conditions, but they also discover new interstellar molecular species. Building up the chemical inventory of astronomical molecules is important to understand how organic matter is produced in the ► [interstellar medium](#) (ISM). Although significant progress has been made in understanding the chemical content and formation mechanisms in interstellar clouds, it is still challenging to predict with certainty which molecular species will be present. A number of species, such as the 3-carbon sugar glyceraldehyde and the simplest amino acid, glycine ($\text{NH}_2\text{CH}_2\text{C}(\text{O})\text{OH}$), have not yet been confirmed in astronomical environments, even though models and the presence of precursor species suggest that these molecules should be present. Most often, a lack of detection can be traced to a combination of the low abundance of a target species and unfavorable physical conditions – namely, source size and temperature. Despite this, a very low-abundance of molecules can be detected by exploiting phenomena such as masing (see, e.g., McGuire et al. 2012).

The following sections focus on recent molecular line surveys of Sagittarius B2(N) near the center of our Galaxy, Orion-KL in the Orion molecular cloud, and TMC-1 in the nearby Taurus molecular cloud. Of the ~200 astronomical molecules detected to date, more than half have been discovered in these regions. The Sagittarius B2 complex contains compact hot molecular cores, molecular ► [maser](#) emitting regions, and ultra-compact sources of continuum radiation surrounded by larger-scale continuum features, as well as more extended molecular material. The Orion-KL molecular cloud includes several distinct molecular sources, with the “hot core,” “compact ridge,” and “low- and high-velocity outflows” the most prominent among them. The TMC-1 dark cloud has a filamentary morphology with diverse clumpy structures, traced by molecular emissions from different dense gas tracers (e.g., H^{13}CO , NH_3 , SO, CCS). These molecular

species peak in abundance at different regions along the TMC-1 filament, the most well-studied of which is the “cyanopolyne peak” (CP) located at the southeastern end of the filament. While chemically simpler than Sgr B2(N), the proximity and narrower line widths of Orion-KL and TMC-1 result in less confused line surveys.

Key Research Findings

The most prolific source of new, astrobiologically relevant molecular detections is the Sgr B2-(N) region. Dedicated searches of Sgr B2(N) using the Green Bank Telescope (GBT), the National Radio Astronomy Observatory (NRAO) 12-m telescope, Herschel, the IRAM 30-m telescope in Spain, the Arizona Radio Observatory (ARO), and the Atacama Large Millimeter/submillimeter Array (ALMA) have resulted in 23 new molecular detections since 2000. These include key prebiotic molecules such as the simplest sugar-related molecule glycolaldehyde (CH_2OHCHO ; Hollis et al. 2004b); a nucleobase precursor, *E*-cyanomethanimine (HNCHCN ; Zaleski et al. 2013); and the molecules with a peptide bond, acetamide (CH_3CONH_2 ; Hollis et al. 2006b) and urea ($(\text{NH}_2)_2\text{CO}$; Remijan et al. 2014, Belloche et al. 2019), among a wealth of other species (see ► [Molecules in Space](#)).

While many of the species detected in Sgr B2(N) have also later been found in the Orion-KL region, only five new molecular detections have been made in Orion-KL since 2000, the most astrobiologically relevant of which is methyl acetate ($\text{CH}_3\text{CO}(\text{O})\text{OCH}_3$; Tercero et al. 2013). More importantly, the different chemical and physical environments of Orion-KL, while still containing many of the same molecular species as Sgr B2(N), provide a comparative testbed for testing the robustness of astrochemical models.

While observations toward the massive star-forming cores Sgr B2(N) and Orion-KL have expanded the interstellar molecular inventory with, predominantly, saturated terrestrial-type molecules, spectral surveys toward the prestellar core TMC-1 have contributed 19 new molecules

to the inventory since 2000, of which the majority is unsaturated carbon-chain molecules (e.g., HC_4NC , HC_{11}N , $\text{CH}_2\text{CHC}_3\text{N}$). Notably, these new molecules include individual aromatic compounds, $\text{C}_6\text{H}_5\text{CN}$, 1- and 2- $\text{C}_{10}\text{H}_7\text{CN}$ (McGuire et al. 2018, 2021). Aromaticity is of particular biological interest as four amino acids out of 20 composing proteins and all the five nucleotides composing generic materials RNA and DNA consist of the functional groups with aromatic structures.

Two other sources, the red hypergiant VY Canis Majoris and the carbon star outflow IRC +10,216, have provided an additional six and 20 new molecular detections since 2000, respectively. These regions have been the primary source of detections of phosphorous-containing species (e.g., HCP, PH_3 , PO, and CCP) as well as a number of metal-containing species (e.g., TiO, TiO_2 , FeCN, AlNC). IRC +10,216 has also been a primary source of molecular anion detections (see, e.g., C_6H^- in McCarthy et al. 2006). Phosphorus is an essential component of life – phosphates (PO_4^{3-}) are ubiquitous in biological systems, from DNA and RNA to phospholipids which are components in cell membranes. Metals, too, play key roles in biological processes (see, e.g., the iron-containing hemoglobin molecules in human blood).

Finally, while the number of new molecular detections resulting from them has been small, the Herschel/HIFI key project “Herschel/HIFI Observations of EXtra Ordinary Sources” (HEXOS) has provided the largest broadband line survey of Sgr B2(N) and Orion-KL to date (Neill et al. 2012; Crockett et al. 2010), extending from ~450 GHz to 1.8 THz. Additionally, as part of its science verification process, an ALMA Band 6 survey of Orion-KL was conducted covering the range from 214 to 246 GHz. The full dataset is publicly available at <https://almascience.nrao.edu/almadata/sciver/OrionKLBand6/>.

Above all else, these detections have shown that a suite of receivers and telescopes working in synergy is necessary to start investigating the questions of the formation, excitation, and distribution of complex organic molecules in astronomical environments.

Basic Methodology

While each survey will be unique due to specific observing and instrumentation considerations, an excellent and detailed overview of general data collection, reduction, and analysis techniques can be found in Neill et al. (2012).

One challenge facing molecular line surveys is the efficient presentation of the data to the community. The survey of the Sagittarius B2(N) region performed with the GBT, the **P**Rebiotic **I**nterstellar **M**olecule Survey (PRIMOS), is changing the way these data are disseminated. The data from the survey is made available quarterly as data is taken and reduced. Dissemination of the fully calibrated data products is available either in simple ASCII text or available through the **S**pectral **L**ine **S**earch **E**ngine (SLiSE), a dedicated data display java-based tool. SLiSE contains functions to overlay possible molecule identifications based on a current line catalog as well as overlaying H and He recombination lines. For a full description of the PRIMOS project and the SLiSE tool, visit: <http://www.cv.nrao.edu/~aremijan/PRIMOS/>.

The SLiSE tool has recently been populated with line survey data from additional sources, primarily legacy data from Barry E. Turner's NRAO 12 m surveys.

Future Directions

Organic materials found in meteorites are considered to be indicative of the chemicals that are present in extraterrestrial sources, such as molecular clouds. A study of the Murchison meteorite by Cooper et al. (2001) finds (in addition to many amino acids and other molecules of potential biological interest) sugars, sugar alcohols (polyols), sugar acids, and other related species with gas chromatography-mass spectroscopy techniques. Some of the sugars take on an important role in the biochemistry of Earth. In space, the simplest sugar-related molecule, glycolaldehyde (CH_2OHCHO), was detected in the Sagittarius B2(N) molecular cloud, but the simplest sugar,

glyceraldehyde ($\text{CH}(\text{O})\text{CH}(\text{OH})\text{CH}_2\text{OH}$), has been sought but not thus far detected. Nonetheless, given the importance of sugars to both terrestrial and interstellar chemistry, the search for more complex sugars, including the base of RNA, will continue into the next generation of astronomical instruments.

Recent results from NASA's Stardust mission show the presence of the simplest amino acid, glycine, in cometary samples returned from comet Wild 2 (Elsila et al. 2009). Yet, the formation mechanism for this building block of life remains something of a mystery due to a lack of any extrasolar detection of glycine.

Finally, at peak operational capacity, ALMA allows the acquisition of 4+ GHz of instantaneous bandwidth (dependent on required spectral resolution) at extremely high spectral sensitivity commensurate with high-resolution spatial mapping. In essence, each pixel in a map toward a target source (e.g., the ALMA science verification data toward Orion-KL) will contain a complete spectral line survey of the area covered by that pixel. ALMA has enabled unbiased molecular line surveys to become a commonplace. Example ALMA molecular surveys include the **E**xploring **M**olecular **C**omplexity with **ALMA** (EMoCA) – survey of Sgr B2(N) (Belloche et al. 2016), the **P**rotostellar **I**nterferometric **L**ine **S**urvey (PILS) – survey of the low-mass protostar IRAS 16293–2422 (Jørgensen et al. 2016), and the **F**ifty **AU S**Tudy of the chemistry in the disk/envelope system of Solar-like protostars (FAUST) – survey of 13 Class 0/I protostars (Bianchi et al. 2020). ALMA is now one of the most prolific facilities of molecular line surveys.

Definition

Molecular simulations refer to techniques that apply theoretical algorithms to study the atomistic details of various physical or chemical processes. It comprises wide range of techniques with diverse purposes, computational costs, and limitations. Three most common approaches are the following. Standard Quantum Chemical (or mechanical, QC, QM) calculations characterize the potential energy surface of the studied systems by considering their electronic structure via the approximate solution of the Schrödinger equation, with different degrees of rigor. Classical molecular dynamics (MD) simulations describe the molecules using a force-field approximation (molecular mechanics, MM) but aim to characterize the free-energy surfaces by including Boltzmann sampling starting from some initial structure. Often the word simulation is used as a synonym to differentiate MD approaches from mere potential-energy computations. Typical MM descriptions do not allow bond breaking and making. Quantum MD differs from classical MD simulations in that it enables sampling of the free-energy landscape of the studied system using QM treatments rather than the MM

approximation; however, the sampling is limited by orders of magnitude. Some QM MD methods include quantum nature of both electrons and nuclei. QM and MM approaches can be combined into hybrid QM/MM methods where a more interesting part of the system is described by the QM approach and the rest of the system by the MM approach. Efficacy of MD methods to sample the free-energy surface may be boosted by diverse enhanced-sampling methods which, however, may bring significant additional approximations compared to the plain MD simulations, namely, prior chemical information about the studied process. In the last 10 years molecular simulations have matured to serve as a basic technique to supplement experimental investigations of astrobiological relevance.

Overview

Across majority of the disciplines natural sciences use experiments as primary method of acquiring information about the studied system. With the development of computing hardware and software at the end of the twentieth century new computer-based methods appeared on the scene, which enable an atomic-level insight into the structure, energy, electronic properties, and dynamic behavior of the studied systems. Since this information is only indirectly available from experiments it opened new horizons in almost all branches of chemical sciences. In particular, computer simulations became instrumental at unraveling reaction mechanisms, interpreting experimentally measured spectra, or at simulating the time-dependent behavior of various molecular properties. Below, an overview of the most frequently used techniques for this purpose is provided.

Basic Methodology

Properties of small systems (consisting of up to ca. 300 atoms) can be most accurately described using quantum chemical calculations. These methods are based on solving the Schrödinger equation:

$$\mathbf{H}\Psi = E\Psi$$

where $\mathbf{H}$ is the Hamilton operator describing the motion of electrons in the studied system, Ψ is the wavefunction, and E is the electronic energy. The two most frequently applied approaches to solve the Schrödinger equation are the so-called wave-function-based and density functional (DFT) techniques.

Wavefunction-based techniques decompose the total wavefunction to contributions coming from each individual electron (ϕ), while DFT-techniques consider the electronic energy as a function of the electronic density (ρ). Since $\mathbf{H}$, Ψ , E , as well as ϕ and ρ are all dependent on the geometrical parameters describing the configuration of atoms in the studied system, the methods can be used to study structure and energy relationship in a wide range of molecular and supramolecular systems.

Force-field based molecular dynamics methods are dedicated to describe more extended systems (like biomolecules). In this approximation the system is considered as being held together by forces, characterizing the interaction of the constituent atoms, whose motion is described by Newtonian mechanics. This approach offers a convenient way to follow inter- and intramolecular motions on timescales up to milliseconds.

Ab initio molecular dynamics simulations provide an insight into the dynamic behavior of molecules combining the Schrödinger equation for energy estimates and the Newtonian-Lagrangian formalism to describe atomic motions. The advantage of this methodology over quantum chemical calculations is that it gives a time-dependent insight into the development of molecular structures. Thereby it enables an easier prediction of molecular mechanisms which relies less on chemical intuition. Another potential advantage of the methodology is a more accurate description of the solvent environment, which often plays a crucial role at mediating chemical mechanisms. Nonetheless, the descriptions of the electronic structures and thus of the energies in quantum molecular dynamics simulations are generally far less accurate than those obtained from static quantum mechanical approaches, such as mere gradient

optimizations and potential-energy scans. It is because in MD simulations major efforts are invested to include the free-energy surface. Thus, the gains from replacing the potential-energy surface description by free-energy surface description may sometimes be outweighed by reduction of the quality of the method used for energy calculations. In many instances conservative potential energy scans using high-quality QM methods may be more reliable than MD simulations with lower-quality methods.

Modern computational methodologies also include combination of the abovementioned techniques, like the popular QM/MM approach, which combines the more accurate wavefunction (QM) treatment with force-field based molecular mechanics (MM) calculations.

Key Research Findings

One of the main areas where computational studies are highly instrumental is the understanding of chemical mechanisms of elementary reactions that could lead to the complexification of extraterrestrial matter. For example, during the last few years numerous studies have dealt with the synthesis of formamide from simple building blocks like formaldehyde, HCO, NH₂, OH, and CH₂NH radicals (Rimola et al. 2018; Barone et al. 2015b; Vazart et al. 2016). These studies utilized quantum chemical calculations. Further, quantum molecular dynamics simulations were used to follow the atomistic details of the elementary processes acting in the Miller-Urey experiment (Saitta and Saija 2014; Wang et al. 2014). Synthesis of the simplest sugar, glycolaldehyde from two formaldehyde molecules bound to two neighboring Ti³⁺ defect sites of anatase surface has been addressed with DFT calculations (Civiš et al. 2016). The computations have shown that the biradical-character of the defect sites facilitates covalent bond formation between the formaldehyde molecules, which would otherwise be energetically highly unfavored.

Quantum chemical calculations and quantum molecular dynamics simulations are frequently applied to understand the mechanism of synthesis

of biomolecular building blocks from simple organic precursor molecules. These studies enable a unique insight into the main steps of molecular evolution leading to the emergence of terrestrial life. Quantum chemical calculations helped to unravel possible mechanistic scenarios for the synthesis of nucleobases from formamide utilizing thermal chemistry (J. Wang et al. 2013a, b) or radical-assisted pathways (Ferus et al. 2012, 2015). It has been shown that radicals created in extraterrestrial impacts (Ferus et al. 2015) or by irradiation with slow protons (Saladino et al. 2017) may trigger a cascade of highly exergonic processes that could end up with the formation of nucleobases or even nucleosides. Glycosidation reactions between nucleobases and ribose have been described (Šponer et al. 2011; Pérez-Villa et al. 2018). Among them thermodynamics of the reaction between triphosphate-activated ribose and nucleobases has been studied by quantum chemical calculations (Šponer et al. 2011). Subsequent *ab initio* molecular dynamics calculations on the reaction of diphosphate-activated ribose and adenine have provided an overestimation of the reaction free energies most likely because of the inaccuracy of the density functional method used (Pérez-Villa et al. 2018). Quantum chemical calculations have unraveled plausible mechanisms for interstellar glycine formation and have suggested that defects formed in interstellar ices upon irradiation with cosmic rays may trigger various radical reactions of cosmochemical relevance (Rimola et al. 2012).

Formation of biopolymers from monomer precursors is another frequently addressed topic of molecular simulations. Quantum chemical calculations have addressed the mechanism of diglycine formation from glycine in various contexts, like TiO₂ (Pantaleone et al. 2018) and silica (Rimola et al. 2006) surfaces, or in the presence of Cu²⁺ cations in solution (Rimola et al. 2007). The latter study has shown that a synergic effect of Cu²⁺ cations and the surrounding water molecules might catalyze peptide bond formation between two glycine molecules. Oligomerization of imidazole-activated nucleotides on montmorillonite has been studied by force-field based molecular dynamics simulations (Mathew and

Luthey-Schulten 2010). Further insights into the process regarding specific absorption of nucleobases on clay-surfaces were obtained from quantum chemical calculations (Mignon et al. 2009; Mignon et al. 2019). Ring-opening polymerization of cyclic nucleotides has been described using density functional calculations (Šponer et al. 2015). The calculations suggested that the reaction requires formation of a stacked ladder-like supramolecular architecture that provides with optimum steric conditions for the trans-phosphorylation reactions.

Classical force-field based molecular dynamics simulations can be used to describe dynamic behavior of simple biomolecules. For example, transient stabilization of overhang geometries in catalytically active geometries was studied using this methodology (Stadlbauer et al. 2015). The process may be relevant at understanding the emergence of the catalytic activity of short oligonucleotide sequences.

Ab initio molecular dynamics simulations are extensively used to study astrophysical processes relevant to extreme pressures resulted by impact shock-waves. It has been shown that shock-compression of a prototypical astrophysical ice-mixture containing NH_3 , H_2O , CO , CO_2 , and methanol may lead to the formation of glycine (Goldman et al. 2010). Recent model calculations have shown that collision of icy interstellar dust grains containing isocyanic acid may produce a wide plethora of complex organic compounds including formic acid, formamide, carbamic acid, or glycine (Cassone et al. 2018).

In molecular spectroscopy high-level quantum chemical calculations are widely used for interpretation of experimentally measured spectra. For example, computed infrared and rotational spectral signatures may help identification of molecules and molecular complexes in the space based on their observed rotational or vibrational spectra (Barone et al. 2015a).

Future Directions

A recent paper has employed density functional calculations to compare the thermodynamic

stability of a large number of biological and non-biological molecules (Jinich et al. 2020). A detailed statistical analysis performed on a group of selected molecules has shown that metabolites are in general more stable than their non-biological counterparts. This study calls for further investigations of thermodynamic stability in terms of its dependence on environmental effects, which might be a key at understanding the conditions leading to the emergence of life from a lifeless matter.

Combination of various techniques used for molecular simulations represents another promising, so far not sufficiently exploited area which could revolutionize our understanding of chemical mechanisms. For example, combination of quantum chemical calculations and quantum molecular dynamics simulations could bring about a better treatment of solvent environment while achieving highly accurate estimates of energetic data.

Molecular Spectroscopy

Agúndez Marcelino

Instituto de Física Fundamental, CSIC, Madrid, Spain

Definition

Molecular spectroscopy is the area of science that studies the absorption and emission of

electromagnetic radiation by molecules and its dependence with wavelength, which results in molecular spectra. The spectrum of a molecule is composed of lines that correspond to radiative transitions between discrete energy levels and thus serves as a fingerprint of the molecule. The arrangement of energy levels of a molecule is determined by the molecular structure, i.e., the kinetic and potential energy of electrons (electronic levels), the motion of the nuclei within the molecule (vibrational levels), and the rotation of the molecule (rotational levels). A good introduction to molecular spectroscopy is given by Herzberg (1950). On the other hand, atoms lack vibrational or rotational motions, and thus their energy levels are exclusively associated to electronic states. Atomic spectroscopy studies the radiative transitions between these states, which usually fall in the UV-visible range of the electromagnetic spectrum.

Definition

Molecular weight is the sum of the masses of the atoms making up a molecule expressed in atomic

units of mass. One atomic unit of mass, or Dalton (Da), is equal to 1/12th the mass of an atom of the isotope ^{12}C of carbon.

Definition

In this entry, by “molecules” we refer to all types of (generally chemically) bound species consisting of two or more atoms. They may be chemically saturated as well as unsaturated, may contain unpaired electrons (i.e., are radicals), or may be charged positively (cations) or negatively (anions). Space refers here to all regions outside the solar system. On occasion, we restrict the discussion only to the ► [Interstellar Medium](#) and circumstellar envelopes in the Milky Way, thus excluding stellar atmospheres as well as extragalactic sources. Molecules in space usually, but not exclusively, refer to those in the gas phase.

Overview

The spectra produced by molecules in space are used to characterize the physical and chemical properties of certain media in space. For example, certain atomic and molecular absorption lines in the visible region observed in stellar atmospheres are used to classify the stars. Atomic and molecular lines play an important role in star formation, as they help to dissipate the energy of molecular clouds. Lines of specific molecules are used to probe the density, temperature, or ionization degree of the interstellar medium or of

circumstellar envelopes. Complex molecules are of particular interest for astrobiology, as their abundances may provide clues to which extent interstellar chemistry may have played a role in the formation of life on Earth or possibly on other planets.

The Molecules in Space web page (<https://cdms.astro.uni-koeln.de/classic/molecules>) of the Cologne Database for Molecular Spectroscopy (CDMS) (<https://cdms.astro.uni-koeln.de>) (Müller et al. 2001, 2005) features an up-to-date table with about 200 molecular species detected in the interstellar medium or in circumstellar envelopes, as well as an up-to-date table with more than 60 molecules detected in extragalactic sources. Tables 1 and 2 are accurate as of mid-July 2018.

Another useful resource is the web page A Hyper-Bibliography of Known Astromolecules (http://www.astrochymist.org/astrochymist_mole.html) of The Astrochymist (<http://www.astrochymist.org/>) with tables of interstellar and circumstellar molecules, cometary molecules, molecules on planetoids, planetary molecules, and molecules in brown dwarfs and stellar atmospheres.

Basic Methodology

All identified molecules in space have been detected by various spectroscopic means, usually by high-resolution (rotationally resolved) gas phase spectroscopy. Molecules in stellar atmospheres have been identified initially by their electronic spectra in the visible region. Later, the observed spectra were extended to the (vacuum) ultraviolet region and to the near-infrared region. Light hydride species such as H₂O, NH₃, and CH₄ may be detected more favorably by their vibrational spectra in the mid- or near-infrared regions. These relatively short-wavelength spectroscopic methods have also some importance for the detection of molecules in the interstellar medium, circumstellar envelopes, or in extragalactic sources, but the majority of detections and (routine) observations are made by radio astronomy, initially carried out in the radio frequency and microwave region below 40 GHz or with wavelengths longer than 7.5 mm. The millimeter region up to about

300 GHz became accessible approximately in 1970, and around 1985 it was possible to carry out observations at submillimeter or far-infrared wavelengths. Already, the upper millimeter region, and even more so the far-infrared region, are faced with the obstacle that the atmosphere is almost or completely opaque in these frequencies, mainly because of the water vapor. Building observatories at high-altitude sites is a partial remedy; putting them on high-flying airplanes or even on satellites is even better because such observatories are (essentially) not affected by water on the line of sight. On the other hand, such airplane- or satellite-borne observatories are much more expensive to run, and the size of the telescope dish is much more limited.

Key Research Findings

Molecules in Stellar Atmospheres

It is important to keep in mind that the presence or absence of atomic or molecular absorption lines in the visible spectra of stars is used to classify stars. O, B, A, and F stars are too hot and their UV radiation too strong for molecular species to survive. A rather large number of molecular species has been detected in the atmosphere of our sun, a G star, but they were detected mostly in sunspots, which are considerably cooler at the surface than is common. TiO can be observed in late K stars and, more strongly, in M and S stars, which are classified mainly by the strengths of TiO lines and in which other transition metal oxides can be seen, such as VO, ScO, CeO, ZrO, CrO, and FeO. Water can be seen in emission in late K and M giants, while C₂ and SiC₂ have been seen in emission in carbon stars. In still smaller, less luminous, and cooler stars, transition metal hydrides have been identified, such as CrH, FeH, and TiH along with NH₃ and CH₄ and, in at least one case, SH.

On occasion, spectral features of molecules show up in the visible in emission. They are thought to originate from the circumstellar envelope of the star rather than the photosphere. As a consequence, in this entry we separate molecules detected in circumstellar envelopes from those detected in the interstellar medium. The exact

Molecules in the Interstellar Medium and in Circumstellar Envelopes

Around 1935, some diffuse absorption lines, suspected to be of molecular origin, were detected in the visible spectra recorded toward certain stars. The diffuse nature of the lines was interpreted as evidence that the carriers of these lines were not associated with the stellar environment but rather with the interstellar medium on the line of sight. Three lines were assigned to CN, CH, and NaH (McKellar 1940); the latter assignment still remains to be confirmed. It was noted that only transitions originating from the lowest rotational levels could be identified unambiguously, suggesting very low temperatures of the environment. In fact, the second rotational level of the CN radical is at 5.43 K. Shortly thereafter, three additional lines were assigned to CH⁺ (Douglas and Herzberg 1941).

Even though radio telescopes had been available since the early 1930s, the first molecule to be detected by this technique, and the fourth

interstellar molecule altogether, was the OH radical in 1963 (Weinreb et al. 1963). Only diatomic molecules had been detected thus far, and it was even speculated by several astronomers that polyatomic molecules, that is, molecules with more than two atoms, could not be formed in the interstellar medium. Therefore, it came as a big surprise that the next two detected molecules, NH₃ (Cheung et al. 1968) and H₂O (Cheung et al. 1969), were polyatomic molecules. Moreover, the molecular lines were observed in emission toward hot-core sources, the rather warm and dense molecular clouds that enshroud young massive stars. Several further light hydride species, molecules consisting of one heavy atom besides H atoms, have been detected. These include SiH₄, CH₄, H₃⁺, and CH₃, which have been observed by infrared spectroscopy because the molecules do not have a permanent electric dipole moment and thus no radio spectrum.

H₂S, HCl, H₃O⁺, CH₂, NH, NH₂, and HF have been detected or observed employing radio astronomy. However, the strong transitions of these light hydride species occur in the terahertz or far-infrared region, which is partly difficult to

access and in part simply not accessible from the ground, requiring radio telescopes on high terrestrial sites, on board of high-flying airplanes such as the NASA's Kuiper Airborne Observatory (KAO), or on board of satellites such as the ► **Infrared Space Observatory (ISO)**; these two missions were in operation in the 1990s. More recently, the Atacama **Pathfinder EXperiment (APEX)** telescope has been built in the Chilean Andes, and the Atacama Large Millimeter Array (ALMA) has started operations at the same site recently. OH^+ (Wyrowski et al. 2010) and SH^+ (Menten et al. 2011) were detected for the first time with APEX. The Herschel satellite was launched 14 May 2009, and ceased to operate 29 April 2013 because the liquid helium coolant was consumed. Numerous Herschel observations were dedicated to light hydride species, in particular to H_2O . Four cationic hydrides, H_2O^+ (Ossenkopf et al. 2010), H_2Cl^+ (Lis et al. 2010), HCl^+ (De Luca et al. 2012), and most recently ArH^+ (Barlow et al. 2013, see also Schilke et al. 2014), were newly detected. The **Stratospheric Observatory for Infrared Astronomy (SOFIA)** started operating in 2010. The **German REceiver At Terahertz frequencies (GREAT)** permits high-resolution observations, e.g., in a frequency gap of *Herschel*/HIFI around 1.3 THz. The first detection of SH in that gap has been reported (Neufeld et al. 2012).

The first polyatomic molecule with two heavy atoms, formaldehyde, H_2CO , was among the very early detected molecules, and it is rather ubiquitous (Synder et al. 1969). Related molecules H_2CNH , H_2CS , and H_2CCO were detected soon thereafter. The isoelectronic diatomic molecules CO, SiO, CS, and SiS were also among the molecules detected very early in the interstellar medium. CO is particularly important as it is the second most abundant molecule in space after H_2 . Moreover, since H_2 is very difficult to observe, CO transitions are frequently observed in order to trace H_2 , although the H_2/CO ratio is thought to vary somewhat as a function of environment (cf. Pineda et al. 2013). SiO is usually viewed as an indicator of shocks.

It is worthwhile mentioning that many atoms have more than one stable isotope. As a

consequence, several ► **Isotopologs** have been detected for molecules that are abundant in certain regions in space. In the case of CO, for example, all six stable isotopologs involving $^{12,13}\text{C}$ and $^{16,17,18}\text{O}$ have been detected. Eight isotopic species have been observed for SiS in the circumstellar envelope of CW Leonis (IRC +10216), all possible combinations involving $^{28,29,30}\text{Si}$ and $^{32,34}\text{S}$ along with $^{28}\text{Si}^{33}\text{S}$ and $^{28}\text{Si}^{36}\text{S}$, thus providing important information on the nuclear synthesis in this late-type star. PO was the first molecule for which the first detection was described in the circumstellar envelope of an oxygen-rich star, namely, VY Canis Majoris.

HCN and HC_3N are quite abundant in all types of region and were also among the molecules detected earliest. The longer chain molecules HC_5N , HC_7N , and HC_9N have been detected in dark molecular clouds, such as TMC-1 (the Taurus Molecular Cloud No. 1), or in circumstellar envelopes, in particular of the carbon-rich star CW Leonis.

In several cases, more than one isomer of a certain formula has been detected. For example, besides cyanoacetylene, HC_3N , isocyanoacetylene, HCCNC , and iminopropadienylidene, HNC_3 , have been detected. More recently, fulminic acid, HCNO , and cyanic acid, HOCN , were detected, which are isomers of the abundant isocyanic acid, HNCO .

Some molecules were detected by radio-astronomical means prior to their laboratory spectroscopic identification. Formylum, HCO^+ (Buhl and Synder 1970), was the first and most notable example. Others include HNC , CCS , HCS^+ , HOCO^+ , and $c\text{-C}_3\text{H}_2$. Several additional examples will be given below.

Many of the cations observed in the interstellar medium or circumstellar envelopes can be obtained formally by protonation of rather stable, closed-shell species, such as CO, N_2 , CS, CO_2 , HCN, H_2O , HC_3N , H_2 , H_2CO , HCl, and C_3 , thus leading to comparatively stable, closed-shell cations, such as HCO^+ and HOC^+ , N_2H^+ , HCS^+ , HOCO^+ , HCNH^+ , H_3O^+ , HC_3NH^+ , H_3^+ , H_2COH^+ , H_2Cl^+ , $l\text{-C}_3\text{H}^+$, and probably H_2NCO^+ . Doubts on the identification of $l\text{-C}_3\text{H}^+$ have become obsolete with the recent recording of

the laboratory rotational spectrum (Brünken et al. 2014). The remaining known cations are in part radicals, SO^+ , CO^+ , OH^+ , SH^+ , H_2O^+ , and HCl^+ , or also closed-shell species, CH^+ and CF^+ . The latter may seem peculiar to some as it contains the most electronegative element, fluorine, in a cation. However, one should keep in mind that it is isoelectronic with CO.

Only a few cyclic species have been detected unambiguously thus far. Besides $c\text{-C}_3\text{H}_2$, these are $c\text{-SiC}_2$, $c\text{-C}_3\text{H}$, H_3^+ , $c\text{-C}_2\text{H}_4\text{O}$, $c\text{-SiC}_3$, and $c\text{-H}_2\text{C}_3\text{O}$. Aromatic molecules, which play an important role in biochemistry, are mostly too big to be observed. However, benzene was detected in the infrared. In addition, certain infrared features are commonly believed to be due to polycyclic aromatic hydrocarbons (PAHs), but the exact nature of these species is not known.

Fullerenes, large molecules built from carbon only and forming near-spherical cage structures, were thought to be present in space ever since they were detected in the laboratory, and attempts were made to identify them as soon as their IR spectra had been measured. C_{60} was particularly promising because the highly symmetric cage structure gives rise to only four infrared-active vibrations. Moreover, it is usually by far the most abundant fullerene in laboratory experiments. C_{70} is less symmetric and usually less abundant, and this applies even more so to somewhat larger fullerene molecules. C_{60} and C_{70} have been identified unambiguously in space for the first time in the circumstellar envelope of a peculiar planetary nebula Tc 1 (Cami et al. 2010). There have been several later and some earlier reports on the detection of fullerenes in space. However, some of them should be viewed with caution, and some may even be incorrect because first, PAH molecules and fullerenes are not cospatial, and second, some infrared features of C_{60} can be caused by molecules, which contain H atoms and are thus not fullerenes.

Methanol, CH_3OH , is very ubiquitous and was the first complex molecule detected in space (Ball et al. 1970). A complex molecule in radioastronomy may be defined as an asymmetric rotor molecule having at least five atoms and which is usually fully saturated or nearly

saturated. CH_3OH as well as some other complex molecules such as dimethyl ether, vinyl cyanide, ethanol, and methyl formate are so abundant and have such a large number of observable transitions that they have been called interstellar weeds. More complex molecules are usually less abundant, and the intensity of spectral features is distributed over many more lines; both these issues make it harder to detect larger complex molecules unambiguously. Ethyl formate, its isomer methyl acetate, and n -propyl cyanide are the largest complex molecules unambiguously detected thus far, and model calculations are compatible with their formation on grain surfaces.

The purported detection of interstellar glycine shall be mentioned in this context. In 2003, the detection of several transitions of glycine, aminoacetic acid, the simplest amino acid, was claimed in three hot-core sources (Kuan et al. 2003). Such sources are particularly line rich. The detection has been disputed (Snyder et al. 2005) because the derived model required several additional lines to be observable, but they were not detected. It is important to note that emission features assigned to a certain molecule may well be stronger than predicted by a model because of overlap, possibly by an unidentified species, but a line cannot be weaker than predicted if the model is correct. Consequently, only an upper limit is currently known for interstellar glycine. As in similar cases for other molecules, this simply means that the abundance of interstellar glycine in the gas phase is too low to be identified unambiguously at present. This situation may change with Atacama Large Millimeter Array (ALMA), as its much greater sensitivity and its greater spatial resolution may be advantageous for the detection of glycine and other complex molecules. Of course, no statement can be made about glycine residing in the solid phase, for example, in interstellar ices or grains. The detection of molecules with low abundances in the solid phase is generally very difficult, as spectral lines of solids, for example, in the infrared, are quite broad and rarely very distinctive. Nevertheless, a plethora of complex molecules have been identified through direct chemical analyses of the Murchison meteorite, including many amino acids. The molecules

show no or only small chiral preference and include many which have not been identified in living beings, indicative of an abiotic origin. These findings suggest that at least some amounts of more complex molecules are formed in certain regions of space. It should be mentioned in this context that aminoacetonitrile, which is considered to be the most likely precursor of glycine, has recently been detected in the high-mass star-forming region Sagittarius B2(N-LMH).

Soon after the interstellar detection of SiO in 1971, vibrationally excited SiO was detected with an unknown carrier (Snyder and Buhl 1974) but correctly identified soon thereafter. Very highly excited SiO (up to $v = 4$ with a vibrational energy of almost 7000 K), HNC (up to about 6000 K), or HCN (up to almost 11,000 K) have been detected in circumstellar envelopes of late-type stars. In addition, vibrational satellites of many more molecules have been detected in hot-core sources or in circumstellar envelopes. They offer the opportunity to probe exclusively the hottest regions in the interstellar medium.

Low temperatures favor exchange reactions of the heavier isotope in molecules with large differences in zero-point vibrational energies. Such differences are particularly large for D/H exchange. HDO was the first deuterated molecule to be detected in space, by Turner et al. (1975). Since then, not only singly deuterated molecules such as DCN, DNC, DCO^+ , NH, and OD have been detected but also doubly deuterated ones, for example, D_2O , D_2S , D_2CO , D_2CS , and $c\text{-C}_3\text{D}_2$, and even triply deuterated ones, namely, ND_3 and CD_3OH .

Molecules containing metals in the chemical sense (not in the very general astronomical sense: every element heavier than helium) remained elusive for quite a while. The first one to be detected was MgNC (Guélin et al. 1986) in the circumstellar envelope of the evolved star CW Leonis, but its correct identification occurred only much later (Kawaguchi et al. 1993). In the meantime, NaCl, KCl, AlF, and AlCl had been detected in the same source. Later, NaCN, MgCN, AlNC, KCN, FeCN, and most recently HMgNC were also detected in that source. Some of these, MgNC, NaCN, AlF, and NaCl, were also detected in other

circumstellar envelopes. AlO and AlOH were the first two metal-containing molecules that were detected in the circumstellar envelope of an oxygen-rich star, VY Canis Majoris. TiO and TiO_2 have been detected (Kamiński et al. 2013). The detection of TiO_2 is particularly interesting as it is thought to act as seed for dust in oxygen-rich late-type stars. It is worthwhile mentioning that TiO as well as some other metal oxides were detected earlier in emission in optical spectra of late-type stars, which is viewed as indicative of a circumstellar origin, in contrast to absorption features, which are thought to originate in the stellar atmospheres. A more detailed account on these issues is intended for the future.

Even though several transition metal compounds have been identified in stellar atmospheres, the only report of this type of molecule in the interstellar medium or in circumstellar environments is the tentative detection of FeO in absorption toward Sagittarius B2(M). The detection is tentative because only one spectral line has been observed. This would also be the first detection of a metal-containing molecule in the interstellar medium (as opposed to circumstellar envelopes) by radio astronomy, although the tentative detection of NaH mentioned above should be kept in mind.

The first molecular anion detected in space was C_6H^- (Kawaguchi et al. 1995); however, it was identified unambiguously only much later (McCarthy et al. 2006). C_4H^- , C_8H^- , C_3N^- , C_5N^- , and CN^- have also been detected. Interestingly, C_5N^- was identified unambiguously even though no laboratory data have been available to date. All these ions are closed-shell species, which can be derived from HC_{2n+2}H or its isoelectronic HC_{2n}CN by abstraction of a proton. There is one weak feature in solid-state infrared spectra that has been attributed to the OCN^- ion, but this assignment appears to be contested. A different weak solid-state feature was assigned to the CO_2 molecule, and this assignment is secure. Other solid-state molecules that have been identified are discussed in the entries on interstellar ices and interstellar dust.

Molecular oxygen, O_2 , was suggested to be abundant at least in certain regions of the

interstellar medium. Its observation is difficult because it has no permanent electric dipole moment, and the magnetic dipole transitions are rather weak. Moreover, observations of O_2 are not possible from ground-based radio telescopes because of the presence of large amounts of oxygen in Earth's atmosphere. Two reports have been published on the unambiguous detection of O_2 using the HIFI instrument on board of the *Herschel* satellite, albeit at levels much lower than already low model predictions and in sources which display a rather peculiar chemistry. In one of the sources, ρ Ophiuchi A, the related molecules H_2O_2 and HO_2 were detected with APEX (Bergman et al. 2011, Parise et al. 2012).

One of the greatest and longest-lasting mysteries in astronomy is the identity of the Diffuse Interstellar Bands (DIBs), which have been detected in absorption in optical spectra toward stars for the first time in 1922. To date, more than 200 of these are known in the far-UV, visible, and IR regions. A fairly recent review has been published by Herbig (1995). The nature of these absorption lines is not clear. Often, they form small groups. High-resolution contour studies suggest that at least some of the carriers, probably even most, are of molecular origin. Many carriers appear to be present in the diffuse ISM, but some may occur in the dense ISM. Observation toward the star Herschel 36 in Sagittarius revealed very unusual band contours for several DIBs (Dahlstrom et al. 2013). Spectroscopic arguments lead to the conclusion that some carriers are likely small molecules consisting of about three to eight atoms whereas others appear to be much larger molecules.

Another interesting issue is the unidentified aromatic infrared emission bands, which are commonly ascribed to PAHs. It is generally accepted that these are the most likely carriers of these emission bands, but again, the exact nature is not clear, in particular because the features are caused by more than one species and may include neutrals as well as charged species. PAHs are also proposed as one possible group of molecules for the carriers of the DIBs.

Molecules in Extragalactic Sources

The molecules detected in external galaxies are thus far a subset of the molecules detected in the interstellar medium, simply because these objects are farther away than our galaxy. Great progress has been made in recent years in terms of investigations into the chemical complexity of external galaxies. As for molecular clouds, the chemical composition depends to a great extent on details of the galaxy, such as size, age, and star formation activity. Starburst galaxies, such as the nearby NGC 253 or M82, show a particularly rich and varied chemistry.

The first molecule to be detected in an external galaxy was OH as early as 1971 by Weliachew, toward the two galaxies NGC 253 and M82. Many other di- and polyatomic molecules have been detected. In recent years, the field has flourished enormously because of molecular line surveys toward several different galaxies and because of extensive observations with the *Herschel* satellite. Particularly noteworthy in this context was a molecular line survey by Muller et al. (2011) of an unnamed foreground galaxy toward the quasar PKS 1830–211. The observations were carried out with the Australia Telescope Compact Array (ATCA). Rest frequencies from the 4 mm wavelength region were red shifted into the 7 mm region. Several molecules were detected for the first time in an extragalactic source in the course of this study. The list of complex organic molecules includes now formamide, methylamine, and acetaldehyde. In addition, detections of di- and triacetylene as well as benzene appear to be secure. The detection of the fullerene C_{60} was also reported. There have also been several reports on molecules in very distant, high-red-shift galaxies, in particular of CO and H_2O .

Future Directions

As indicated already, ground-based instruments such as APEX, ALMA, the IRAM 30 m instrument, NOEMA, as well as the *Herschel* satellite, along with the Stratospheric Observatory for Infrared Astronomy (SOFIA), have provided

and will continue to provide extensive opportunities to carry out observations in the terahertz (or far-infrared) region which, among other interesting results, are relevant to the detection of light hydride molecules. The ALMA has begun early science observations, and some results have been published already; it will provide unprecedented sensitivity and spatial resolution. This should facilitate studies of complex molecules in dense molecular clouds. It may well become possible to detect much larger molecules, though these are frequently easier to detect at longer wavelengths. Moreover, it will surely be beneficial for the study of circumstellar envelopes, where metal-containing molecules may be easier to detect, or of extragalactic sources. It will also be possible to study comparatively small-scale structures in nearby galaxies. In addition, the increase in sensitivity will open new opportunities to study very distant galaxies routinely. Other radio interferometers, such as the Sub-Millimeter Array (SMA), the Plateau de Bure Interferometer (PdBI), or the Jansky Very Large Array (JVLA) at lower frequencies, will remain or even grow in importance as they undergo various forms of upgrade. In addition, a number of interesting detections have been made with the Green Bank Telescope (GBT) and others at higher frequencies, e.g., with the IRAM 30 m telescope. The field of astrochemistry is thus expected to flourish tremendously in the next few decades.

Monod's Conception on the Origins of Life

Michel Morange

Centre Cavailles, USR 3308 CIRPHLES, Ecole normale supérieure, Paris Cedex 05, France

Keywords

DNA · Oparin · Origin of life · RNA world

History

Jacques Monod's interest in the question of the origin of life came late in his career, when he tried to summarize the major conceptual transformations resulting from the rise of molecular biology, first in lectures, and then in his influential book *Chance and Necessity*.

For Monod, the formation of the first living organisms had been a highly improbable event, and Earth was probably the only place in the Universe harboring life. The formation of living organisms can be explained by the laws of physics and chemistry, but it was unpredictable. This opinion was based on the results recently obtained in molecular biology, which showed the exquisite nature of the mechanisms involved in the transmission of genetic information through generations, and its use at each generation. An even more serious obstacle to the origin of life was the necessity for organisms to possess two different types of macromolecules: DNA, to store the genetic information; and proteins, the active agents of living cells. The origin of life meant the simultaneous formation of these two types of macromolecules. There are tight relations between these two macromolecules: DNA codes for proteins, and proteins are required for the use of the information encoded in the DNA. Not only did both types of macromolecules have to appear simultaneously, but they had to have from the beginning at least a part of their complex relations.

Monod was probably philosophically happy with this conclusion. It justified scientifically his feeling of an absurd Universe and of the loneliness of human beings in it.

Monod did not see in the scenarios elaborated by the Russian biologist Oparin a way to overcome these difficulties. Not only did these scenarios fail to take into account the most recent molecular descriptions, but their author was compromised by the support he gave to Lysenko under the Soviet regime. Monod distrusted Oparin and his models.

Forty years later, the situation is very different. The discovery of the catalytic role of RNA has led to the hypothesis of the existence of an RNA world that preceded the present living world. The difficulties outlined by Monod have not been totally removed, but ways to overcome them are being explored. Most present-day biologists consider that the formation of simple forms of life was not so difficult, and that the search for these forms of life on other planets deserves to be supported.

Monomictic Breccia

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Monogenic breccia](#)

Definition

A *monomictic* or *monogenic breccia* is a sedimentary rock composed of angular clasts derived from a single lithology. The term monomictic also refers to a specific process of brecciation produced by rock shearing and granulation (cataclasis) during a tectonic event or by dislocation metamorphism (a type of metamorphism of local extent, associated with fault or shear zones). If the dislocation metamorphism is related to a meteorite impact, the breccia may be termed a *monomictic impact breccia*. Reiff (1978) by discussing monomictic breccia complexes in impact structures such as Ries (Germany) coined a new term *monomictic movement breccia*. In impact structures, a drastic brecciation of whole rock complexes to silt fraction grain size (<50 µm) requires intense movement under very high confining pressure.

Synonyms

[Holophyletic](#)

Definition

In classical taxonomic and phylogenetic literature, a monophyletic group, also called a clade, is defined as an assemblage that contains an ancestor and all its descendants. This term is most often applied to define groups of organisms that derive from a ► [common ancestor](#), which form monophyletic taxa or clades (e.g., animals or cyanobacteria). However, it is used by molecular phylogeneticists also to define particular groups of DNA, RNA, or protein sequences in ► [phylogenetic trees](#) (e.g., different protein families derived from gene duplications). Monophyletic groups are based on the identification of synapomorphies, which are shared derived characters (e.g., a skull and a distinct head are synapomorphies of vertebrates). This criterion allows differentiating monophyletic groups from paraphyletic groups (those containing an ancestor and part of its descendants, such as the reptiles) and polyphyletic groups (those that do not contain the last common ancestor of their members, such as the flying animals, including disparate members like insects, birds, and bats).

Monosaccharide

Shin Miyakawa
Kamagaya, Chiba, Japan

Synonyms

[Simple sugar](#)

Definition

Monosaccharides are monomeric ► [carbohydrate](#) molecules. Examples include glucose, fructose, galactose, xylose, and ► [ribose](#). 2-Deoxyribose and ribose are constituents of DNA and ► [RNA](#), respectively. Many of the carbon atoms attached to hydroxyl groups are chiral centers, giving rise to a number of isomeric forms. Many monosaccharides are unstable over geological timescales. The half-lives for the decomposition of ribose, for example, are 73 min at 100 °C, and 44 years at 0 °C at pH 7. They can be formed in the ► [formose reaction](#) from ► [formaldehyde](#). Monosaccharide-like compounds have been found in carbonaceous chondrites, and one of the ketoses, dihydroxyacetone ($\text{HOCH}_2\text{COCH}_2\text{OH}$), was identified in the extract of Murchison meteorite.

Montmorillonite

Gözen Ertem
National Institutes of Health, Bethesda, MD, USA

Keywords

Catalyst · Cation exchange · Clay minerals ·
Oligomerization · Origin of life

Definition

Montmorillonite is a ► [clay](#) mineral of the smectite group, which also includes nontronite and saponite. It was first discovered in 1847 in Montmorillon in the Vienne region of France. It is usually white, gray, or pink with shades of green or yellow as a result of the metal oxide impurities it contains. It is often found in compact or lamellar masses, but never in large individual crystals. Its specific gravity varies between 1.7 and 3.0. It has a hardness of 1–2 in the Mohs scale (the Mohs scale ranges between 1 and 10, where 1 and 10 correspond to talc and diamond, respectively). Chemically, it is a hydrated aluminum silicate containing small amounts of magnesium, iron, sodium, calcium, and potassium as a result of isomorphic substitutions. The nature of these cations and their ratio within the mineral structure vary with the source of montmorillonite.

Overview

Montmorillonite (Grim 1968) has a layer structure with 2:1 arrangement: Each layer is composed of three sheets. Two outside sheets, called tetrahedral sheets, contain silicon ions, Si^{4+} , tetrahedrally coordinated to oxygens. The middle sheet, called the octahedral sheet, is made up of aluminum ions, Al^{3+} , surrounded by oxygens in octahedral coordination. The general formula of montmorillonite may be represented as

where IV and VI denote the tetrahedrally and octahedrally coordinated cations, respectively. The term $(x + y + z)$ is the total of substitutions in the octahedral and tetrahedral sheets. Theoretically, montmorillonite is assumed to have formed from pyrophyllite $[(\text{Al}_2)(\text{Si}_4\text{O}_{10})(\text{OH})_2]$.

During the formation of clay minerals by weathering, some of the Si^{4+} ions in the tetrahedral sheet are replaced by cations of similar size (isomorphic substitution), usually Fe^{3+} , and some of the Al^{3+} cations are replaced by Mg^{2+} . These replacements result in excess negative charge, which is counterbalanced by so-called interlayer cations held between the layers. Since sodium is one of the most abundant cations in nature, most clay minerals contain Na^+ as an exchangeable cation. The extent of isomorphic substitutions is defined as cation-exchange capacity, CEC, of montmorillonite and expressed as milliequivalents of interlayer cation/100 g of clay. Most montmorillonites have a CEC of about 100.

Because of its large surface area, about $800 \text{ m}^2/\text{g}$, montmorillonite is widely used as an absorbent for toxins, hazardous chemicals, and heavy metal cations. Montmorillonites can absorb water and swell to about 20 times of their dry volume and give rise to permanent suspensions of gel-like masses.

Hydration, or solvation, of interlayer cations causes the layers to expand. Due to this expansion, organic molecules, such as amines, alcohols and polyalcohols, nucleic acid bases, nucleosides, and oligomers, can enter the interlayer of

montmorillonite. This expansion capability, which is a result of the isomorphic substitutions, gives the montmorillonite its catalytic properties. Extensive studies have demonstrated that montmorillonite serves as an effective catalyst for the ► [oligomerization](#) of activated nucleic acid monomers (Ertem et al. 2010). These reactions are very significant in terms of ► [origin of life](#) studies as was first suggested by John D. Bernal (1949).

Moodies Group

Christoph Heubeck
Institut für Geowissenschaften, Friedrich-Schiller-Universität Jena, Jena, Germany

Definition

The Moodies Group is the uppermost stratigraphic unit in the ► [Barberton Supergroup](#), the sedimentary-volcanic fill of the ► [Barberton Greenstone Belt](#), South Africa and Swaziland. It is one of the oldest well-preserved shallow-water sedimentary sequences on Earth, reaches up to

approximately 3.7 km in thickness and is, north of the Inyoka Fault, $3,224 \pm 1 - 3,219 \pm 10$ Ma old (Heubeck et al. 2013). Its stratigraphic architecture, facies, petrography, age, and style of deformation allow detailed insights in mid-Archean surface conditions. The equivalent to the Moodies Group in Swaziland is the Malolotsha Group (Lamb 1984, 1987).

Overview

Hall (1918) originally defined the Moodies Series, named after a local land surveyor, to include all sedimentary units in the BGB. The modern definition and use of the Fig Tree and Moodies Groups go back to Visser et al. (1956). Anhaeusser (1976) subdivided the Moodies Group in three formally defined formations (Joe's Luck, Clutha, and

Baviaanskop) and a number of informal lithostratigraphic members. Eriksson (1977) suggested an alternative subdivision in five fining-upward sequences (MD1 through MD5).

Structure

Moodies strata are mostly preserved in large (ca. 5–15 km long, several km wide) synclines. Geologists describe them as being “tightly to isoclinally folded, commonly northward overturned, and doubly plunging, refolded about vertical axes. Fold axis plunge may become vertical and even overturned” (Figs. 1 and 2). Figuratively speaking, the synclines appear somewhat like horizontally sliced bananas, the anticlines between them like mushrooms. The resulting high strain is concentrated in brittle shear zones and is presumably also expressed by widespread simple shear in (usually poorly exposed) fine-grained intervals;

Moodies Group,

Fig. 1 Along-strike view of Moodies Group strata in the Saddleback Syncline, central BGB. The fluvial-deltaic and tidal strata dip steeply to the *right*; stratigraphic up is to the *left*

Moodies Group,

Fig. 2 Downplunge view (towards the SW) of the Saddleback Syncline in the central BGB, illustrating tight to isoclinal folding of sandstones and interbedded silty sandstones

in contrast, the sandstone-dominated units on the fold limbs are nearly free of strain. Syn-deformational deposition, expressed as inward-facing progressive unconformities, has been documented from the southern (Lamb 1987) and northern (Heubeck and Lowe 1994b) margins of the BGB, suggesting that at least part of the Moodies Group was eroded from the cover of rising plutons nearby and shed as alluvial fans into subsiding elongate troughs.

It is unclear to which degree Moodies strata represent a single coherent depositional system. The continuity of the key marker unit, the Moodies basaltic lava (MdL), over >60 km along strike and across four structurally separated synclines north of the Inyoka Fault suggests that at least some of the Moodies basins were integrated during middle Moodies time (all of Moodies time may have been only a few Ma long). In contrast, the uneven distribution and thickness and the highly distinctive clast composition of the basal conglomerate and of the stratigraphically highest conglomerates indicate that the Moodies basin was dominated by local, not regional, dispersal processes in early and late Moodies time.

Quartzose sandstones assigned to the Moodies Group south of the mid-BGB Inyoka Fault lack K-feldspar, appear to represent a higher metamorphic grade, lack recognizable marker beds, and are preserved in greatly reduced thickness. Their temporal and paleogeographic relationship to the “classic” Moodies stratigraphy north of the Inyoka Fault is uncertain.

Lithologies and Facies

The Moodies Group is dominated by sandstones. Siltstones and conglomerates are subordinate in most localities; shale is very rare. Volcanic rocks include one regional basaltic lava unit, numerous discontinuous and thin rhyodacitic tuffs, and at least one local ignimbrite. Minor jaspilite and BIFs, interbedded with siltstones, serve as important regional marker units. Sandstone composition varies widely and ranges from quartzarenites to subarkoses (up to 22% feldspar) and to volcanic litharenites and chertarenites (Heubeck and Lowe 1999). Eriksson (1977, 1978, 1979, 1980) and Heubeck and Lowe (1994a) distinguished between alluvial, fluvial, deltaic, shoreline, tidal, and offshore facies. Eriksson et al. (2006) describe a well-exposed fluvial-to-marine facies transition; Eriksson and Simpson (2002) provide data which may bear on Archean tidal cycles, and Simpson et al. (2012) outlined features of likely eolian deposition (Fig. 3).

The base of the Moodies Group is transitional from concordantly underlying volcanics and volcanoclastics of the Schoongezicht Formation (uppermost unit of the Fig Tree Group); conventionally, the contact is placed at the lowest occurrence of polymict (i.e., composed of clasts of many different lithologies) conglomerates, overlying the feldspar-porphyry-dominated Schoongezicht conglomerates. The top of the Moodies Group is not exposed because BGB strata are unconformably overlain by strata of the Transvaal Supergroup. Moodies stratigraphy has been best investigated

Moodies Group,

Fig. 3 Thin section photomicrograph of a subquartzarenite of unit MdQ1, Saddleback Syncline. Grains of monocrystalline quartz, chert, quartz-sericite-mosaic, and microcline are embedded in a sparse sericitic-calcareous matrix

in the thick and subvertically dipping limbs of the Stolzburg, Saddleback, and Eureka Synclines and in the Moodies Hills Block.

Life

Following a cursory description (Heubeck and Lowe 1994a), Noffke et al. (2006) interpreted abundant crinkly laminations in the MdQ1 member of the Moodies Group in the Saddleback Syncline (and beds of uncertain stratigraphic position in the Dycedale Syncline) as microbial mats. Their observations were specified and expanded by Heubeck (2009), Gamper et al. (2012) and Homann et al. (2015). Independently, Javaux et al. (2010) extracted organic-walled macro-spheres up to 300 μ in diameter from stratigraphically poorly constrained siltstones of the Moodies Group from drill cores of a mine; these findings are not yet documented from outcrop.

The microbial laminae (Fig. 4) likely represent extensive photosynthetic ► **microbial mats** in sub-, inter-, and supratidal facies. The stratigraphically lowest microbial mats are interbedded with conglomeratic, poorly channelized cross-bedded sandstones and intervening thin mudcracked shales; they may thus be fluvial in facies. The presumably high tidal ranges, however, likely blurred the distinction between fully marine, tidal, and fully terrestrial facies in the Archean.

Age

Centimeter- to decimeter-thick rhyodacitic ash beds, occasionally lapilli bearing, are not

uncommon in the Moodies Group; in addition, several felsic dikes, probably radiating from the Kaap Valley Pluton or marginally associated sub-volcanic feldspar porphyry bodies, crosscut beds of the Moodies Hills Block and of the Eureka Syncline along the northern margin of the BGB (Layer et al. 1996; Heubeck et al. 2013). Inferred depositional ages of the volcanic beds throughout the Moodies Group obtained through single-zircon U-Pb dating are nearly indistinguishable from each other. They indicate that Moodies deposition began $\sim 3,224 \pm 1$ Ma and had ended by $\sim 3,219 \pm 10$ Ma (Heubeck et al. 2013).

Tectonic Setting

A considerable number of tectonic settings have been proposed to be represented by the Moodies Group. They include a stable continental margin, evolved from a continental rift (Eriksson 1979, 1980); a foreland basin setting north of an ancient orogen made up of the Ancient Gneiss Complex and the Onverwacht rocks (Jackson et al. 1987; Eriksson et al. 1994); an initially extensional and strike-slip-related setting followed by basin collapse (Heubeck and Lowe 1994b); and an arc-related or back-arc basin setting. Kisters et al. (2003, 2010) and Lana et al. (2011) favored a strongly extensional basin. The contemporaneity of solid-state pluton uplift adjacent to the belt along with evidence of syndeformational deposition (Fig. 5) suggests deposition in one or several

Moodies Group,

Fig. 4 Outcrop photograph of microbial laminations near the base of the Moodies Group, Saddleback Syncline. *Dark green* laminations consist of kerogen. They form complex domes and isolated tufts, trace microchannels, and foreset laminae in medium-grained tidal and fluvio-deltaic sandstones. Coin is 16 mm in diameter

Moodies Group, Fig. 5 Progressive intraformational angular unconformity along the northern limb of the Saddleback Syncline (Heubeck and Lowe 1994b). *Green arrow* indicates stratigraphic-up direction. Wedge-shaped alluvial conglomerates facing toward the synclinal axis

(to the *left*) are erosionally truncated and in turn overlain by alluvial conglomerates. The angular unconformity dies out toward the synclinal axis. A similar relationship was documented at the southern margin of the BGB by Lamb and Paris (1988)

elongate subsiding troughs between the rising plutons. Such a scenario would relate poorly to modern plate-tectonic settings.

Future Directions

The age data collectively suggest that 3.7 km-thick Moodies strata were deposited syn-tectonically within 1–14 Ma and represent a very highly resolved stratigraphic window into Archean surface processes, comparable in resolution to many Quaternary sections with mean depositional rates of about 1 mm/a. The Moodies Group thus likely preserves numerous examples of short-term bio-geo-atmospheric interactions.

Moodies Group, Microbial Mats

Martin Homann

Institut für Geologische Wissenschaften, Freie Universität Berlin, Berlin, Germany

Definition

The Middle Archean ► [Moodies Group](#) (~3.22 Ga, ► [Barberton Greenstone Belt](#), South Africa), Earth's oldest known well-preserved shallow-water siliciclastic sequence, includes several units with common microbial mats which thrived in the photic zone of a tidally influenced shoreline. The fossil mats are preserved as kerogenous laminations up to 1 mm thick, are interbedded with medium- to coarse-grained sandstones and rare gravel beds (Fig. 1), and were early silicified. SEM observations of the laminae show interwoven and bundled microbial filaments (1–3 µm in diameter), confirming mat biogenicity.

Microbial communities in the Moodies Group colonized at least three major depositional settings, each associated with a specific mat morphotype: (1) In the *coastal plain*, mats are typically flat and occasionally overgrew gravel beds; (2) tufted microbial mats, which reach 1–2 cm in height, are exclusively present in the *supratidal zone* and are commonly associated with gas and/or fluid escape structures; and (3) wavy-crinkly morphotypes are characteristic of the *intertidal zone*.

**Moodies Group,
Microbial Mats,**

Fig. 1 Photograph of a part of a polished slab of microbial mats (*dark laminae*) from the Moodies Group. Kerogenous laminae are interbedded with medium- to coarse-grained sandstone. They are of the wavy-crinkly morphotype and show small domes

Modern tufted mats are dominantly built by filamentous cyanobacteria, suggesting that their ancient counterparts may have been constructed by filamentous organisms and required early mineralization for structural support.

It is likely that Moodies microbial mats were (at least in part) photosynthetic communities because other potential metabolic strategies can be excluded, the morphology indicates phototactic behavior, and the mats consistently occur in shallow-water/photoc-zone facies.

Moon Treaty

Acronyms

UN	United Nations
UNOOSA	United Nations Office for Outer Space Affairs

Definition

The “Agreement Governing the Activities of States on the Moon and Other Celestial Bodies,” also referred to as the Moon Treaty, was adopted by the United Nations General Assembly in 1979.

This multilateral treaty elaborates on the provisions of the Outer Space Treaty as applied to the Moon and other celestial bodies, providing that those bodies should be used exclusively for peaceful purposes and their environments should not be disrupted. The Agreement states that the Moon and its natural resources are the common heritage of mankind and that an international regime should be established to govern the exploitation of such resources.

The United Nations Office for Outer Space Affairs (UNOOSA) is responsible for promoting the international, peaceful use, and exploration of space and the utilization of space science and technology for sustainable economic and social development. UNOOSA also assists the UN Member States to establish legal and regulatory frameworks to govern space activities and strengthens the capacity of developing countries to use space science technology and applications for development.

Giant impact hypothesis · Impact cratering · Moon · Origin of the solar system

Definition

The origin of the Moon deals with the process by which our satellite came into existence about 4.5 Gyr before the present. The origin process explains the chemical, isotopic, and geological framework of the Moon, as well as how it attained its initial orbit around the Earth.

History

Planetary scientists' ideas on the origin of the Moon have changed drastically since 1984, in the aftermath of a seminal conference in Kona, Hawaii, when the theory of the "giant impact" emerged (Hartmann et al. 1986). This theory is now widely accepted, although many important questions remain to be answered (Jolliff et al. 2006). The need for a new theory of the Moon's origin grew out of the confrontation between the three "classical" theories (capture, fission, and coaccretion) and the flood of new data on the Moon provided by the U.S. Apollo missions from 1969 to 1972. Analysis of the lunar rocks returned by these missions along with geophysical measurements and photographs made both on the surface and from orbit yielded a picture of the Moon that is incompatible with any of the classical theories and provided the foundation for an entirely new approach to the Moon's origin (Stevenson 1987).

Overview

The Moon's Present State

It has been known for over a century that the Moon is, on average, much less dense than the Earth. The modern value of the Moon's mean density is 3.344 g/cm^3 . Although this is suggestively close to the density of the Earth's mantle, it is less than 0.6 of the Earth's mean density and is taken to indicate that the Moon lacks a significant metallic iron core. The small size of its core is required by the ratio:

$$C/MR^2 = 0.3935 \pm 0.0011$$

where C is the maximum moment of inertia, R the radius, and M the mass of the planet Hartmann et al. (1986). The value measured for the Moon is nearly the same as that of a uniform sphere (0.4000). The Moon's metallic iron core is less than 450 km in radius and comprises less than 4% of the Moon's total mass. Although the Moon has no intrinsic magnetic field at present, remnant magnetism has been found in ancient lunar crustal rocks, suggesting the activity of a dynamo early in its history.

The Moon's crust is composed predominantly of the plagioclase-rich rocks ► [anorthosite](#) (the light-colored areas of the Moon's surface), norite, and troctolite, which appear to have crystallized from melts. Seismic and gravity investigations show that the average thickness of this crust is less than about 60 km. The crust is generally thicker on the farside of the Moon than on the nearside, where it locally thins to 20 km beneath the lava-filled mare basins. The lunar mantle extends to a depth of about 1,000 km and is composed mainly of the minerals olivine and pyroxene. The mantle and crust appear to have separated chemically about 4.5×10^9 years ago in a global melting event known as the lunar "magma ocean." The rare earth element europium (Eu), which has an affinity for plagioclase, is enriched in the crust but depleted in the mantle, a complementary pattern suggesting that the two separated during an era of widespread melting in the ancient Moon. Below about 1,000 km depth, seismic waves are strongly attenuated, indicating

rocks below this depth are partially molten. Very small “moonquakes” occur regularly between 700 and 1,100 km depth in response to tidal stresses.

The estimated bulk chemistry of the Moon shows both striking similarities and differences with the Earth’s mantle. The oxygen, potassium, chromium, and several other isotopic signatures of the Earth and Moon are basically identical, indicating a close relation between the two bodies. The major elements Si and Mg are generally similar in both bodies. Iron oxide, however, appears to be more abundant in the Moon than in the Earth’s mantle. The refractory elements Al, Ca, Cr, Ti, and U may be enriched in the Moon compared to the Earth, while the volatile elements Na, K, and Rb are strongly depleted. The highly volatile molecule H₂O is present at only a few parts per million in the most volatile-rich samples. Elements with an affinity for metallic iron (siderophiles) such as Ni, Ir, Mo, and Ge are much more strongly depleted in the Moon than in the Earth’s mantle. The Earth and Moon are thus chemically distinct at the same time as being isotopically nearly identical.

The ratio between the Moon’s mass and the Earth’s mass is 0.0123, larger than any other planet-satellite pair in the solar system except for Pluto/Charon. The Moon’s mean distance from the Earth is currently 60.3904 Earth radii, and the Moon is receding from the Earth at a rate of 3.74 cm/year due to tidal friction. An important fact is that the Moon is not now in the Earth’s equatorial plane, to which its inclination varies between 18.4 and 28.6° as its orbit precesses. The angular momentum of the Earth-Moon system is anomalously high compared to the other planets (except, again, for the Pluto/Charon system). If all of the mass and angular momentum of the Earth-Moon system were put into the Earth, it would rotate with a period of only about 4 h.

Age of the Moon

Isotopic studies of the lunar rocks show that the Moon and Earth are nearly identical in age, 4.5×10^9 years. High-precision studies using the isotope pair ¹⁸²Hf and ¹⁸²W, however, indicate that the Moon is younger than the Earth by 10–30 Myr (Jacobsen 2005), although the precise

age difference is currently a matter of debate (Touboul et al. 2007).

Classical Theories of Origin

There are three basic models for lunar origin that were under study at the time of the Apollo landings. Although there are many variants of these models and even some hybrids, three pure “end-members” can be described under the headings of Fission, Intact Capture, and Coaccretion.

Fission

One of the best-studied theories of the Moon’s origin is derived from the high angular momentum of the Earth-Moon system. In 1879, G. H. Darwin suggested that if the Earth ever did spin with a period of 4 h, it would be subject to rotational instabilities, and a chunk (or debris ring in more modern theories) would spin off the equator and could eventually clump together outside the Roche limit to form the Moon. This theory neatly predicts the Moon’s depletion in metallic iron and is consistent with the similarity of [▶ oxygen isotopes](#) and major elements in the Earth and Moon. However, it does not account for the differences in refractory or volatile elements, incorrectly predicts that the Moon was once in Earth’s equatorial plane, and altogether sidesteps the question of how the Earth began in a state of such anomalously rapid rotation.

Intact Capture

The most direct way to explain the differences between the Moon and the Earth is to suppose that they were formed in different parts of the solar system under different conditions and that the Earth subsequently captured the Moon. This theory also has a long history of investigation, none of which has succeeded in overcoming the problem that capture of a Moon-size body is a very low-probability process. Capture is plausible only if the relative velocity of the Earth and Moon is very low, and for the velocity to be low, the two bodies must have formed at nearly the same radial distance from the Sun, making it hard to understand how they could differ chemically. Although capture could account for some of the differences between the Earth and Moon, their similarities are unexplained by this theory.

Coaccretion

If the Moon neither broke off the Earth nor came from elsewhere in the solar system, then perhaps it grew along with it. A group of theories posit that the Moon accumulated from debris in orbit around the growing Earth. These theories run immediately into the problem of explaining how the Earth happened to acquire a metallic iron core totaling about 32% of its mass while the Moon remained nearly iron free. Although a variety of “compositional filters” have been proposed, most of which rely on the differences in mechanical strength between iron and silicate planetesimals, none has gained general acceptance as a plausible explanation of the density difference between the Moon and Earth. Coaccretion theories also have difficulty explaining the other chemical differences, predict that the Moon grew in the Earth’s equatorial plane, and, for somewhat more subtle reasons, fail to account for the angular momentum of the Earth-Moon system. Nevertheless, theories of this kind enjoyed widespread support at the time of the Apollo landings.

The Giant Impact Hypothesis

The idea that the Moon might have been formed in an unusually large impact with the proto-Earth was suggested independently by Hartmann and Davis (1975) and by Cameron and Ward (1976). Earlier, in 1970 and 1972, A. E. Ringwood had argued that the chemistry of the Moon indicates that its material was derived from the Earth’s mantle by impacts, but he was unable to propose a plausible dynamic scenario in which this occurred (Ringwood 1970, 1972). Cameron and Ward (1976) noted that the angular momentum problem would be solved if the Earth were struck obliquely by a Mars-size protoplanet at a speed roughly comparable with Earth’s escape velocity, 11.2 km/s. The angular momentum of the Earth-Moon system does not provide enough information to determine separately the angle of impact, mass, and velocity of the projectile, but given plausible values of these parameters, a mass ranging from about 1/2 to 3 times the mass of Mars is probable. Hartmann and Davis (1975) approached the problem by examining the distribution of protoplanetary sizes in the solar nebula near the end

of planetary accretion. They concluded that in addition to a few large protoplanets, there was probably several times that number half as large, still larger numbers one-fourth as large, and so on down to the smallest sizes. In their view, the last stages of planetary accretion in which these objects were swept up must have been characterized by extraordinarily violent collisions among these planetary-size objects. G. W. Wetherill also discussed this view in detail in his 1985 numerical simulations of the final stages of planetary growth (Wetherill 1985).

Current work on the Moon’s origin has focused on computer modeling to evaluate the detailed consequences of an impact with a Mars-sized body. After initial efforts by the teams of A. G. W. Cameron and W. Benz and H. J. Melosh and M. E. Kipp in this area, R. M. Canup has taken this work to much higher resolution and used better material models to provide increasingly realistic simulations of the process (Canup and Righter 2000; Canup 2004). Her results show that the giant impact does explain most of the dynamic features of the Moon and so this model is currently the preferred explanation of the Moon’s origin. These simulations show that the impact initially ejects most of the iron-nickel core material of the projectile but this falls back onto the Earth after a single orbit, merging with the core of the Earth in a catastrophic event that melts most of the Earth’s mantle. Meanwhile, several lunar masses of gas, dust, and molten material from both the Earth’s mantle and the projectile enter an orbit around the Earth, while the bulk of the projectile’s mass merges with the proto-Earth. Later, on a time scale of years, about half of the orbiting debris reimpacts the Earth while a similar mass merges into a single body at a distance of several Earth radii - the proto-Moon.

In spite of the success of the giant impact model, the similarity in oxygen and other isotopes between the Earth and Moon is still not fully explained because even the best computer models predict that approximately 70% of the Moon’s material is derived from the projectile, not from the Earth. Unless the isotopic composition of the projectile was fortuitously nearly identical to that of the Earth, this is inconsistent with the observed

close agreement of the oxygen isotope ratios in the Earth and Moon. Several attempts have been made to resolve this problem, but at present no proposal is universally accepted. The giant impact scenario may require some revision in the future. Nevertheless, it remains the only model that is consistent with most of the dynamic and chemical facts presently known about the Moon.

Evolution of the Moon After Its Formation

The Moon's surface is scarred with thousands of impact craters ranging in size from the South Pole-Aitken basin with a diameter of 2,600 km down to the smallest micrometeoroid craters only a few microns across. The flux of meteoroid impacts has not been constant through time, however. During the era of "heavy bombardment" between the Moon's origin and about 3.8×10^9 years ago, the impact flux was at least several thousand times the present flux. The great basins that form the basis for lunar stratigraphy have ages that date from near the end of this period (Wilhelms 1987). Lava rose from the Moon's mantle and flowed out over its surface, partly filling the low-lying nearside mare basins for nearly 10^9 years after their formation. The bulk of lunar volcanism then ceased about 3×10^9 years ago. The Moon is a one-plate planet: ► [plate tectonics](#) never occurred on the Moon because its small size prevents the vigorous convection necessary to break cold surficial rocks into discrete plates. The Moon's few geologic faults all seem to be related to impact basins or sagging of the crust beneath the load of extruded lavas, although an ancient "tectonic grid" or fabric of faults and fractures in the crust may have developed as it was flexed by tidal forces during the Moon's recession from the Earth. Subsequent to its violent birth and active youth, the Moon has lapsed into a state of geologic senescence marked only by occasional impacts and the regular, tidally triggered moonquakes.

Earth-Moon system

Definition

The Moon is the only large planetary object in the inner solar system to orbit and affect a ► [terrestrial planet](#). It may have supported the *Earth's* specific evolution as a habitable environment. As an integral part of the Earth-Moon system, it is witness to more than 4.5 Ga of solar system history, and it is the only planetary body except Earth for which we have samples from known locations. The Moon's simple composition and its restricted geological activity provide insights into elementary planetary processes. The Moon is thought to be the product of an early planetary collision of a Mars-sized body with Earth (cf. Hartmann et al. 1986; Jolliff et al. 2006; Jaumann et al. 2012).

Earth and Moon form a celestial system with a common center of mass located at about 1700 km beneath the Earth's surface (Fig. 1). With a diameter of 3474 km, the Moon is the fifth largest satellite in the solar system. Its surface covers less than one tenth that of the Earth's surface, its volume is about 2%, and its mass is only 1.2% of that of Earth. Its equatorial surface gravity is 1.622 m/s^2 , about 1/6 (17%) of that on Earth.

The lunar rotation slowed down early in its history due to frictional effects associated with

tidal deformations and became locked into a synchronous state, keeping the same face turned toward the Earth at all times. A complete orbit around the Earth takes 27.3 days (the orbital period), whereas periodic variations in the geometry of the Earth-Moon-Sun constellation are responsible for the phases of the Moon, which repeat every 29.5 days (the synodic period).

The Moon's density is 3340 kg/m^3 (=cubic meter) with a bulk crustal density of 2580 kg/m^3 (Wieczorek et al. 2013), and its ► [rocks](#) are of a relatively simple mineralogical composition. Compared to Earth the Moon is depleted in iron and other siderophile elements (cf. Heiken et al. 1991; Jolliff et al. 2006) and shows depletion in ► [volatile](#) elements, in particular H_2O and OH. The lunar topographic relief ranges from -9000 m in the South Pole region to about $+11,000 \text{ m}$ on the northern far side (Scholten et al. 2011; Jaumann et al. 2012).

Basic Methodology

Our knowledge about the moon is based on telescopic observations from Earth, observations by spacecraft from the lunar orbit, measurements on

M

Moon, The, Fig. 1 Earth-Moon relations

the lunar surface by manned and unmanned landing missions, and the analyses of lunar samples brought to Earth by the Apollo (382 kg) and Luna (326 g) missions and about 120 lunar ► [meteorites](#) (48 kg) that have been collected on Earth to date (cf. Jaumann et al. 2012). Remote sensing using passive sensors in the optical wavelength range and active laser and radar detection technology supported by in situ field work yield information concerning the geological processes that formed the Moon, allowing its entire history to be studied with respect to its impact-related, volcanic, tectonic, and ► [space weathering](#) evolution. Spectral measurements in all wavelength ranges from high-energy gamma rays to the mid-infrared provide the overall surface composition and major mineralogical content of rocks, whereas geochemical details and the origin, differentiation, and evolution of the lunar rocks have been deduced from the returned samples.

Key Research Findings

Since the Apollo 11 astronauts returned the first samples, the Moon is known to be a differentiated planetary body as a result of fractional crystallization of a postulated ► [magma](#) ocean (cf. BVSP 1981; Heiken et al. 1991; Jolliff et al. 2006) beginning immediately after its accretion at 4.527 ± 0.01 Ga (Kleine et al. 2005).

The lunar ► [crust](#) is composed of four major distinct rock types developed from geochemical differentiation as well as mechanical destruction and mixing. (1) Pristine highland rocks of igneous origin are composed of older (4.5–4.3 Ga) ferroan anorthosites and slightly younger (4.43–4.17 Ga) troctolites, norites, gabbroanorthosites, and dunites (the Mg-suite) that mark the transition between magma-ocean-related magmatism and serial magmatism (cf. Heiken et al. 1991; Jolliff et al. 2006). (2) Pristine basaltic volcanic rocks are generally enriched in FeO and TiO₂ and depleted in Al₂O₃ (cf. BVSP 1981; Heiken et al. 1991; Jolliff et al. 2006) resulting in olivine and pyroxene-rich and plagioclase-poor mare ► [basalts](#) and pyroclastic deposits. Most of the lunar basalts erupted between 3.9 and 3.0 Ga from partial melts of a non-tholeiitic anhydrous

basaltic magma located at various depths, mostly >350 km (cf. BVSP 1981; Heiken et al. 1991; Jolliff et al. 2006). (3) Polymict clastic breccias were produced by single or multiple impacts and are a mixture of different rock types from different locations containing various fractions of clastic rock fragments and impact melt varying in texture, grain size, and composition (Stöffler et al. 1980).

The uppermost lunar crust consists of an unconsolidated debris layer called regolith of fine-grained pristine crystalline rock and mineral fragments and agglutinates – aggregates of small particles welded together by glass produced in micrometeorite impacts (cf. Heiken et al. 1991; Jolliff et al. 2006).

On a macroscopic scale the lunar surface has been modified by three major processes: impact, volcanism, and tectonics. Impacts are geological events that eject, dislocate, and redistribute material on all scales, building up morphologies from small bowl-shaped to large flat-floored craters partly refilled by fallback material and mass wasting. With increasing impact energy the relaxation of the compressed crust piles up a central peak and even multi-ringed mountain chains. As the number of impacts on a surface unit is correlated with its exposure to the cosmic bombardment, the frequency distribution of craters is a measure of its age (cf. Neukum et al. 2001; Jaumann et al. 2012). The Moon is stratigraphically divided into five time units: Pre-Nectarian (>4.1 Ga), Nectarian (4.1–3.85 Ga), Imbrian (3.85–3.2 Ga), Eratosthenian (3.2–0.8 Ga), and Copernican (<0.8 Ga) (Wilhelms 1987).

Several large impacts penetrated the lunar crust, triggering the major lunar volcanic activity. Unlike Earth the Moon has not had ► [plate tectonics](#) and has thus preserved the witnesses of its thermal history from the beginning through basaltic deposits and volcanic landforms. Lunar basalts are concentrated on the near side mostly in ► [impact basins](#). They cover 17% or 7×10^6 km² of the lunar surface and amount to 1% of the crustal volume (Head 1976). Lunar volcanism was active for almost 3 Ga, starting at about 4.0–3.9 Ga and ceasing at ~1.2 Ga (Hiesinger et al. 2003). Geomorphologic features of volcanic origin include lava flows, volcanic domes, cones, and lava tubes (sinuous rilles). Tectonics is related

to both impact and volcanism and expresses extensional and compressional features such as faults, graben, dikes, and wrinkle ridges.

The lunar interior is divided into three major zones: the crust, the ► [mantle](#), and the core (Fig. 2). The thickness of the crust is on average 38.5 ± 4.5 km (Wieczorek et al. 2013), thicker on the far side and thinner on the near side, causing a dichotomy with the center of mass being offset from the geometric center by 1.9 km (cf. Jolliff et al. 2006). Seismic data indicate that velocities are almost constant in the upper mantle down to 560 km. Then there is a discontinuity due to a change in composition: below ~ 1150 km seismic waves are attenuated, suggesting partial melting (cf. Heiken et al. 1991; Jolliff et al. 2006).

Although the existence of a lunar core is still debated, geophysical data are consistent with a core being composed of either a molten Fe-FeS-C metallic alloy with a radius of less than 375 km or a slightly larger molten Fe- and Ti-enriched silicate composite (cf. Heiken et al. 1991; Jolliff et al. 2006). The Moon has no global ► [magnetic field](#), yet all measurements indicate that some rocks of the lunar crust are magnetized (Hood et al. 2001). Although this observation is consistent with the Moon once having possessed a dynamo (which would require a metallic core), it is also consistent with transient magnetic fields generated by impact events (cf. Jolliff et al. 2006).

The atmospheric conditions on the Moon are those of the interplanetary space. Nevertheless

Moon, The,

Fig. 2 Conceptual cross section of the lunar crust and interior. (Adapted from Stöffler 1990; Konopliv et al. 1998; Kahn et al. 2000)

10^5 – 10^7 molecules/cm³ (from solar wind, surface sputtering, and radioactive decay) or a total of 10^4 kg gas is in a neutral lunar “atmosphere” (Heiken et al. 1991). More common in the lunar environment is dust generated by hypervelocity impacts of fast projectiles (13–18 km/s) producing secondary material by striking the surface, of which a fraction leaves the surface, forming a lunar dust envelope (Heiken et al. 1991). There also are a variety of energetic particles (solar wind and galactic cosmic rays, mostly consisting of protons, electrons, and heavier nuclei) in the Moon’s environment. The lack of an essential atmosphere and the weak remnant magnetic field cause this radiation to directly interact with the surface, yielding measurable alterations of the uppermost material (Heiken et al. 1991).

Numerous models have been proposed to explain the origin and formation of the Moon (Hartmann et al. 1986), including fission from Earth, co-accretion with Earth, gravitational capture, and giant impact (cf. Hartmann et al. 1986; Cameron and Benz 1991). The most striking constraints for the formation of the Moon are its bulk composition and the high angular momentum of the Earth-Moon system (Jolliff et al. 2006), which can best be explained by a giant collision of the proto-Earth with a large object in the early solar system history (cf. Hartmann et al. 1986; Jolliff et al. 2006; Jaumann et al. 2012). This large object, like the proto-Earth, must have been already differentiated with the iron and siderophile elements concentrated in the core. After collision most of the dense material was incorporated in the Earth’s mantle and core, while the outer portions of the impactor and the crust and upper mantle of the Earth have been ejected into an Earth orbit where the material re-accreted to form the Moon. The energy released by the impact and the re-accretion produced large-scale melting that formed the magma ocean. Cooling and density segregation of crystals from the melt formed the primordial low-density plagioclase-rich lunar crust, accompanied by the sinking of mafic minerals to the bottom of the magma ocean, followed later by a concentration of potassium (K) and rare earth elements and

phosphorus (KREEP)-rich materials (cf. Jolliff et al. 2006). The melts produced from the Moon’s heterogeneous interior were extruded, triggered, and facilitated by crustal weakening and excavation due to massive impacts.

Recently H₂O and OH have been confirmed in the south polar crater Cabeus (Jonas 2009; Colaprete et al. 2010). In addition, absorptions at 2.8–3.0 μm have been detected in cooler high-latitude surface regions associated with fresh craters (Pieters et al. 2009). For silicate bodies, such features are typically attributed to OH- and/or H₂O-bearing materials. It is assumed that the formation and retention of this OH and H₂O are either a result of hydration processes in the lunar surface, or else it is created continuously by solar-wind protons interacting with oxygen-rich surfaces produced during micrometeorite impact on lunar soil particles (Pieters et al. 2009). Due to the fact that the lunar axis is almost perpendicular to the ► [ecliptic](#) (Fig. 1), the larger polar craters are permanently in shadow. These cold traps accumulate ► [water](#) ice molecules either resulting from impacts or from hydration or solar-wind-related OH/H₂O production processes (cf. Anand et al. 2012; Jaumann et al. 2012). Although these discoveries demonstrate that the Moon has water, the small amounts, of the order of parts per million (ppm), still show that the Moon is extremely dry. Nevertheless the polar cold traps and the lunar regolith are candidate sources of volatiles for human exploration (cf. Anand et al. 2012).

Given that the Moon is very likely to be responsible for the 24-h rotation period of Earth that it stabilizes Earth’s obliquity, which otherwise would be subject to large chaotic variation (Laskar et al. 1993), and that it raises substantial tides in the Earth’s oceans, the Moon acts as a climate regulator, supporting the habitability of Earth for complex life forms and catalyzing the evolution of life on our planet.

MORB

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble,
France

Synonyms

Mid-ocean ridge basalt

Definition

MORB is the rock (basaltic in composition) formed by eruption of magma at the oceanic spreading centers (► [mid-ocean ridges](#)) to form the ► [oceanic crust](#). It forms as the upper mantle passively upwells and partially melts where lithospheric plates diverge at the oceanic spreading centers. It is commonly porphyritic with plagioclase or more rarely ► [olivine](#) phenocrysts. Eruption under water produces ► [pillow lava](#) interspersed with rare sheet flows. The basalt is relatively magnesian (5–11% MgO) and characterized by high Al₂O₃ content (12–18%) and low concentrations of K₂O. In N-MORB (normal MORB), the incompatible elements are depleted relative to more compatible elements, reflecting derivation from depleted (previously melted) upper mantle.

Cell motility

Definition

Motility refers to the ability of organisms to move actively, consuming energy in the process. There are structural and functional differences between prokaryotic and eukaryotic motilities.

Overview

Prokaryotic motility. Many ► [prokaryotes](#) are motile due to the presence of a special structure, the flagellum; certain prokaryotic ► [cells](#) can move along solid substances by gliding, and planktonic microorganisms can also regulate their position in a water column using gas vesicles. Prokaryotic flagella are long, thin helical appendages attached to the cell at one end. Flagella can have a polar (attached to one or both cellular ends) or a peritrichous (inserted around the cell) position. The filaments of prokaryotic flagella are composed of subunits of a protein called flagellin. In ► [Bacteria](#), flagellin is highly conserved, suggesting that motility has deep evolutionary roots. However, in Archaea, several different flagellins have been described, and the flagellar structure seems to be quite different from that of Bacteria, although the flagellar

function seems to be similar. In addition to the filament, the flagellum has a motor with two components: the rotor (basal body) and the stator. The motor is anchored in the cytoplasmic ► [membrane](#) and cell wall through a series of rings. In gram-negative bacteria, a third ring is anchored to the lipopolysaccharide membrane. The rotary motion of the flagellum is imparted from the basal body. The energy required for rotation comes from the proton motive force.

Some prokaryotes move across solid surfaces in a process called gliding. In cyanobacteria, it is known that a polysaccharidic slime is secreted. As the excreted slime adheres to the surface, the cell is pulled along. In other systems, specific motile proteins anchored in the cytoplasmic and in the outer membrane seem to propel the cell forward, in a type of continuous ratcheting mechanism. Gliding motility plays an important role in cell-to-cell interaction. Spirochetes have an unusual mode of motility, based on a torque-like motion produced by a special type of flagella called endoflagella.

Cellular motility. The internal structural network of eukaryotes comes from proteins that form filamentous structures called microfilaments and microtubules. Together, these structures form the cell cytoskeleton. Microfilaments are about 8 nm in diameter and are polymers of the protein actin. These fibers form scaffolds throughout the cell. Microtubules are larger filaments, about 25 nm in diameter, and are composed of the protein tubulin. Microtubules assist microfilaments in maintaining cell structure. Microfilaments and microtubules also play an important role in cell motility, both in the movement of internal cell structures and in the movement of the organism itself. Prokaryotic cells, although much smaller than eukaryotic cells, produce structural and functional homologues of actin and tubulin.

Eukaryotic motility. Cilia and flagella are organelles of motility present in many groups of eukaryotic microorganisms. Cilia are essentially short flagella that beat in synchrony to propel the cell, usually quite rapidly, through the medium. Flagella are long appendages that push the cell, more slowly than cilia, by means of a whiplike

motion. The flagella of eukaryotic cells are structurally quite distinct from bacterial flagella and do not rotate. In cross section, cilia and eukaryotic flagella are quite similar. Each contains a bundle of nine pairs of microtubules surrounding a central pair of microtubules called the axoneme. A protein, dynein, is attached to the tubulin of the microtubules and functions as an ► [ATPase](#). Movement of both cilia and flagella is similar. In both cases, movement involves the coordinated sliding of axonemal microtubules against one another in a direction toward or away from the base of the cell. This movement confers the whip-like action that propels the cell. A number of algae and protozoa are motile, using filaments; some protozoa use cilia; and some diatoms have gliding motility, similar to that of prokaryotes. Most cells in plants and complex animals are immobile. However, animal cell motility is responsible for muscle contraction.

Mount McRae Shale

Nicholas Arndt

Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Definition

The *Mount McRae Shale* is a 2.5-Ga-old unit of mudstone, siltstone, chert, iron formation, and dolomite in the Hamersley basin of the ► [Pilbara craton](#), Western Australia. It is characterized by a high concentration of organic carbon (~2–8 wt%), abundant disseminated pyrite (~1 to ~10 wt% S in the bulk rocks), and pyrite nodules (~1–10 cm radius). Analysis of S and Fe isotopic compositions of carbonaceous pyritic shale recovered in the NASA-sponsored Astrobiology Drilling Program, as well as Os, Tl, and Mo isotopes, revealed variations in isotopic compositions. These later have been linked to changes in the composition of the ocean and the atmosphere as well as to fluctuations and a temporary and episodic rises of atmospheric oxygen that preceded the ► [Great Oxygenation Event](#) (GOE) at 2.32 Ga.

mRNA Display

Burckhard Seelig

Department of Biochemistry, Molecular Biology and Biophysics & BioTechnology Institute, University of Minnesota, St. Paul, MN, USA

Definition

The mRNA display method is an *in vitro* selection technique that allows the isolation of functional proteins from large combinatorial libraries of polypeptide variants (Roberts and Szostak 1997; Nemoto et al. 1997). This technology has been used to determine the probability of occurrence of proteins with a specific function in the vast sequence space of all possible polypeptides.

Overview

Functional proteins might have originated from early peptides that initially were synthesized as random amino acid polymers. In order to test the likelihood of such random mixtures containing functional polypeptides, a large number of polypeptides need to be tested as this likelihood might be low. While there are numerous methods to sample mixtures of proteins, the approach that can search the largest number of mutants is most suited to address this question. mRNA display is a technique that can sample libraries of up to 10^{13} randomized protein variants. In mRNA display, the messenger RNA is covalently attached to the very protein that it encodes (Fig. 1), thereby

mRNA Display, Fig. 1 mRNA-displayed protein.

A protein is covalently linked to its encoding messenger RNA. This link is established during the *in vitro* translation reaction of the mRNA, which prior has been modified with puromycin (P)

rendering each single protein molecule directly amplifiable (Roberts and Szostak 1997; Nemoto et al. 1997). This stable link of genotype and phenotype enables the selection of novel protein binders or enzymes. mRNA display was instrumental to show that about 1 in 10^{11} random sequence proteins have the ability to bind ATP (Keefe and Szostak 2001), and that an enzyme with a novel activity and structure can be found in randomized protein libraries (Seelig and Szostak 2007; Chao et al. 2013).

Mucin

Daniel A. Petrash
Environmental Geochemistry and
Biogeochemistry, Czech Geological Survey,
Prague, Czech Republic

Definition

Mucin is a deeply branched and compositionally conserved type of glycoprotein secreted by the epithelial cells of animals. Approximately 80% of mucin's molecular weight is comprised of oligosaccharides attached by *O*-glycosidic bonds to threonine, serine, or proline residues in the polypeptide backbone of the protein core. At the amino and carboxyl terminals, regions can be high in cysteine with extensive disulfide bonding. In marine realms, this polyanionic biomacromolecule forms a gel-like substrate that regulates the speciation and mobility of dissolved metals in bioturbated sediments. Such capability is relevant for distinctive biomineralization processes that occur at the vicinity of burrow walls.

History

Early in the twentieth century, mucins were already known as a compositionally conserved class of “proteid” compound with carbohydrates exhibiting an “ethereal acidic nature” (e.g., Levene 1900). For a long time, glycoproteins, such as mucins, did only receive minor scientific attention. Yet, as summarized by Montreuil (1980), several attempts to define the structure of the glycoproteins had been completed by the 1960s. During the 1970s, the scientific community discovered many other aspects of their

properties and structural characteristics. Researchers working on such macromolecules during the 1980s refined previous structural considerations and elucidated some of their functions. They observed that mucins appear to exert a critical role in the movement of mineral ions and organic compounds of low molecular weight at the level of cell-surface membranes (Montreuil 1980). It is now known that glycoproteins are involved in nearly all biological processes. The structure and function of the different compounds categorized as mucin glycoproteins are reviewed by Strous and Dekker (1992). In environmental samples, the specific role and contributions to dissolved organic carbon (DOC) remineralization and biomineralization of mucin-type glycoproteins remain to be fully explored (but see Lalonde et al. 2010; Petrash et al. 2011; Verdugo 2012; Hannides and Aller 2016).

Mud Volcanism

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Sedimentary volcanism](#)

Definition

Mud volcanism is the extrusion at the surface of Earth of mud and water driven by gases (dominantly CH₄, CO₂ or N₂) in hydrocarbon-bearing basins (Mazzini and Etiope 2017). Mud and water can accumulate in specific places, forming a little “volcano-like” edifice, then the term “mud volcanoes.” Around mud volcanoes, communities of thermophilic prokaryotes and biofilms develop. Pitted cones, mounds, and flows occurring in the northern lowlands of Mars may have formed through processes akin to terrestrial mud volcanism with release of gas from sedimentary strata via gravity destabilization. Similar processes have been suggested for

Multicellular Organisms

Synonyms

[Complex organisms](#); [Pluricellular organisms](#)

Definition

Multicellular organisms are those composed by multiple ► [cells](#). They are classified in 13 major groups of terrestrial living beings, including animals, plants, fungi, ciliates, algae, and foraminifera. The number of cells per organism range from some tens to up to several million. The cells in a multicellular organism are usually varied, differentiated, and specialized.

Overview

The evolutive path toward multicellularity seems to be not particularly challenging, as different groups of multicellular organisms seem to have evolved independently (Rokas 2008). Also, it is possible to follow the invention of multicellularity in separate major clusters of organisms within the 13 main groups, as they are well known to be polyphyletic. In general, aquatic organisms became multicellular because the daughter cells did not separate completely during cell division, while land multicellular organisms formed by the aggregation of a multinucleate syncytium (a multinucleated mass of cytoplasm that is not separated into individual cells). The ultimate cause for the origin of multicellularity may be found in the advantages that an increase in body size brings. Becoming large makes it easier to be shielded from variations in physico-chemical conditions of the external surroundings, as the multicellular organisms build their own internal environment (Bonner 1999). Also, the division of labor among different groups of specialized cells may pose some selective advantages (Michod and Roze 2001). Multicellularity requires cell-to-cell communication, cooperation, and specialization (Niklas and Newman 2013).

The primeval multicellular organisms first emerged during the Paleoproterozoic period. Techniques of molecular chronology suggest that multicellular organisms originated about 2–2.5 Gyr ago. And molecular analyses are coincident with the fossil record, pointing to evidence for macroscopic life during the Paleoproterozoic era (2.5–1.6 Gyr ago). But the available fossil record of the development of early multicellular organisms is sparse. It is noteworthy that the microscopic fossil record of unicellular protists and bacteria is extensive in the sedimentary rocks of almost any age, but fossils of multicellular organisms are extremely rare in Pre-Ediacaran sediments (the Ediacaran is the period that precedes the Cambrian, from 630 to 540 Ma ago). The reason may be that Precambrian animals were soft-bodied, thin, and small, with no hard covers or skeletons that would have been easily preserved in the sediments. This is so because Proterozoic animals thrived in an atmosphere dominated by greenhouse gases with a very

low concentration of oxygen (Donoghue and Antcliffe 2010). The oxygen reached their tissues by diffusion, a slow and ineffective mechanism, and they lacked a circulatory system. Consequently, small size was a reasonable evolutive solution to take advantage of the atmospheric composition of the Earth at that time.

It was only at the beginning of the Ediacaran that some of these soft-bodied animals began to leave a record in the fossil sequence: the footprint of their bodies in the mud. These first animal remainders are now called the *Ediacaran fauna*. Some of them were similar to modern jellyfish, worms, arthropods, or starfish, and therefore started to include some harder parts, such as articulated legs or primitive shells. The beginning of the Cambrian period witnessed a rapid increase in the fossil record of multicellular life on the surface of the Earth. This boost in the fossil evidence, known as the Cambrian explosion, was probably triggered by a significant rise in the concentration of atmospheric oxygen (Smith and Szathmáry 1997). As they were able to grow larger and thicker bodies, animals began to develop hard body parts, such as external skeletons or shells, to gain advantages against competitors or predators. Therefore, it is very likely that the widespread fossil record of the Cambrian animals, compared with their meager Precambrian ancestors, has more to do with the ease of fossilization of the new hard parts of their bodies than with an actual increase in the animal populations in the biosphere at the beginning of the Phanerozoic.

Mutagen

Ester Lázaro
Molecular Evolution Laboratory, Centro de
Astrobiología (CSIC-INTA), Madrid, Spain

Keywords

Base analogs · Evolution · Genetic damage ·
Genetic diversity · Mutation · Radiation

Definition

A mutagen is a physical, chemical, or biological agent able to increase the occurrence of ► [mutations](#) above the spontaneous level. Mutations produced by the action of mutagens are called induced mutations. The effect of most mutagens is due to their ability to modify a particular ► [nucleic acid base](#) or to become incorporated into the nucleic acid. As a high amount of mutations have deleterious effects on ► [fitness](#), exposure to mutagens usually has negative consequences. Nonetheless, at early evolutionary stages, certain environmental mutagens could have had a positive effect, increasing the extent of genetic diversity accessible to ► [natural selection](#).

Overview

Among chemical mutagens, the most important are nucleic acid base analogs – which due to their similitude with natural bases can be incorporated into DNA or RNA during replication – and compounds that produce chemical alterations in the bases (Drake and Baltz 1976). The result in both cases is the induction of erroneous base pairing at the next replication round. Intercalating agents are another type of chemical mutagens that insert themselves between adjacent bases or base pairs, increasing the frequency of insertions and frame-shift mutations. In turn, the main physical mutagens are ultraviolet light and ionizing radiation (X and gamma rays); the latter also includes the atomic and subatomic particles emitted by radioactive elements. ► [UV radiation](#) is mutagenic because of its potential to cause cross-linking between adjacent thymine or cytosine bases and to produce free radicals that can alter the bases in the nucleic acids. Ionizing radiation also generates free radicals and reactive ions able to act directly in the nucleic acids by breaking certain chemical bonds. Regarding biological mutagens, the most relevant ones are viruses or genetic elements that can be incorporated into the genomic DNA (Leib-Mösch and Seifarth 1995). However, the number of molecules and physical agents that can interfere with the faithful replication of the genetic material or with the mechanisms able to repair the damage is probably much higher than is currently known (Friedberg et al. 2005). As an example, compounds that interfere with the pathways of synthesis of nucleotides can cause nucleotide concentration imbalances that may also be mutagenic.

Some mutagens could have played a relevant role in evolution, especially in the early Earth prior to the emergence of cellular life. At those stages, all the biochemical processes, including nucleic acid replication, were strictly dependent on the physical-chemical conditions of the environment, which probably had a strong mutagenic potential due, among others effects, to limited availability of substrates, presence of diverse chemical compounds, or absence of an ozone layer protecting the Earth's surface from ultraviolet light (Rothschild and Cockell 1999). At these early times, increased generation of mutations could have had positive effects,

contributing to the large genetic diversity that would be necessary to select new functions, increasing the biological diversity in this way. Mutagens could also have played an important role as a selective pressure, causing the emergence and fixation of current mechanisms able to prevent or repair the damage produced in the genetic material.

Mutagenesis

Ester Lázaro
Molecular Evolution Laboratory, Centro de Astrobiología (CSIC-INTA), Madrid, Spain

Definition

Mutagenesis is the process by which the genetic information of an organism is modified in a heritable way. It includes the generation of spontaneous and ► [mutagen-induced](#) ► [mutations](#). As most mutations have deleterious effects on fitness, mutagenesis usually has negative consequences,

which can even result in population extinctions when selective processes are not able to compensate the mutational force. Mutagenesis induced by ultraviolet light and other environmental agents could have played a relevant role in shaping the broadness and nature of the diversity attained by the first systems containing genetic information that arose in the primitive Earth. Site-directed mutagenesis is a powerful technique that allows scientists to introduce mutations at defined positions in the genomic sequence.

Cross-References

- [Mutagen](#)
- [Mutation](#)

Mutant

Ester Lázaro
Molecular Evolution Laboratory, Centro de Astrobiología (CSIC-INTA), Madrid, Spain

Definition

A mutant is a gene or an individual bearing a ► [genotype](#) that differs from the reference wild-type sequence in one or more positions. The genotypic differences can give rise to new phenotypic characteristics or not, depending on the effects that ► [mutations](#) have on fitness. The frequency at which a specific mutant is represented in a population depends on the rate at which the particular mutations it carries are produced and on its selective value. The presence of a certain amount of mutant individuals is beneficial for a population, as it makes possible ► [adaptation](#) to the continuous changes in the selective pressures.

Keywords

Adaptation · Evolution · Fitness · Genetic alteration · Replication error

Definition

A mutation is any inheritable change in the genetic information (DNA or RNA) of biological entities, be they cells, viruses, or replicating molecules. In multicellular organisms, only mutations produced in the gametes (germinal cells) are transmitted to the progeny. Despite the negative effects that most mutations have on ► [fitness](#), they play an essential role in living systems, contributing to the generation of the genetic diversity necessary for the action of ► [natural selection](#) (Bell 2008). In the long term, the concerted action of mutation and ► [selection](#) has made biological evolution possible (Woodruff and Thompson 1998), from the first replicating molecules to the complex organisms living in the current world.

Overview

Mutations can be produced spontaneously as a result of natural cellular processes, such as the generation of errors during genome replication or the occurrence of modifications in the nucleic acid bases (Lewin 2008). The replication ► [errorrate](#) largely depends on the presence of corrector or “proofreading” activities in the enzymes that carry out the copying process. Mutations can also be induced by the action of physical or chemical agents known as mutagens.

Mutations can be classified according to the extent of the genetic material affected. Those affecting only one or a few nucleotides are referred to as the following: (1) point mutations, when a single nucleotide is exchanged for another; (2) insertions, when one or more extra nucleotides

are added; and (3) deletions, when one or more nucleotides are eliminated. Point mutations can be transitions (substitution of a purine by a purine or of a pyrimidine by a pyrimidine) or transversions (substitutions of a purine by a pyrimidine or vice versa). Insertions and deletions, when produced in the coding region of a gene, can cause changes in the reading frame (frameshifts), giving rise to genic products that differ largely from the original. Alterations that involve large genomic regions often are the result of either ► [recombination](#) or the movement of transposable elements. Relevant examples are gene duplication (an important mechanism of generation of new functions) and loss of genes.

Mutations in the coding regions of genes can be non-synonymous (when they change the encoded amino acid), synonymous (when the mutated ► [codon](#) codes for the same amino acid), or nonsense mutations (producing stop codons). Non-synonymous changes often change the function of the encoded protein, whereas synonymous changes are frequently assumed to be neutral. This, however, can be uncertain, since they can affect nucleotides involved in functions different from coding, such as transcription regulation or interaction with other molecules.

The effects of mutations on fitness can be deleterious, beneficial, or neutral, although their sign often depends on the environment, on the degree of adaptation of the population, and on the genomic context (Eyre-Walker and Keightley 2007). Therefore, many neutral or even deleterious mutations can have a selective value when the environment changes. In general, beneficial mutations are very rare, although they can reach high frequencies in populations or even become fixed, thanks to the action of natural selection.

Definition

Mythology studies the myths, which are narratives based on imaginary facts that present collective significations in a civilization. Myths have no scientific fundaments, but they are interesting for the understanding of prescientific representation of civilizations.

N

***N*-Carbamoyl Amino Acid**

Laurent Boiteau
Institut des Biomolécules Max Mousseron,
Montpellier, France

Synonyms

[CAA](#)

Definition

N-carbamoyl amino acids (CAAs) are prebiotically relevant organic compounds bearing both carboxylic (–COOH) and ureido (–NH–CO–NH₂) functional groups. They are precursors to amino acids (in which an amino group –NH₂ replaces the ureido group) and to hydantoins, the latter being cyclic, dehydrated forms of CAAs. CAAs are products of the ► [Bücherer-Bergs synthesis](#), hence possible side products of the prebiotic formation of amino acids. Alternately, CAAs are also reversibly formed by spontaneous reaction of ► [urea](#) or cyanic acid with amino acids. CAAs are possible prebiotic precursors of peptides through the formation of *N*-carboxyanhydrides (NCAs), for example, by nitrosation. Since the ureido group bears chemical energy, the spontaneous hydrolytic decomposition of CAAs is also able

to induce NCA formation, which is suggested by the formation of peptides in low yield from CAAs.

NAI

Michel Viso
Innovaxiom, Paris, CX, France

Definition

The NASA Astrobiology Institute (NAI) was established by the US National Aeronautics and Space Administration in 1998 in order to develop the field of astrobiology and provide a scientific framework for future spaceflight missions. The NAI consisted of a set of competitively selected “teams” at research institutes distributed

throughout the United States, with affiliated institutions in 12 other countries; ► [NASA](#) referred to this network as a “virtual” institute. Each team typically included scientists from several institutions who collaborated on related astrobiological questions. The NAI Director and a small staff were located at the NASA Ames Research Center in Mountain View, California. The NAI concluded activities at the end of 2019, at which time the remaining teams were folded into what NASA calls Research Coordination Networks (RCNs). The RCNs will bring together researchers who are funded from a variety of sources into interdisciplinary, topically focused research groups. NASA currently plans to have five RCNs, which will focus on the following research topics: prebiotic chemistry and the early Earth; early metabolism, evolution, and complexity; life detection on other worlds; habitable worlds (initially focused on ocean worlds); and exoplanet system science.

Nakhla

Ana-Catalina Plesa
German Aerospace Center (DLR), Institute of Planetary Research, Berlin, Germany

Definition

Nakhla is an 18-kg Martian meteorite discovered in El Nakhla, Egypt, in 1911. It is the first of the nakhlites subgroup of the SNC meteorites and the first one to suggest aqueous processes on Mars. Its crystallization age has been estimated to 1.38 Ga using different isotopic systems. This clinopyroxenite is thought to have crystallized in thick lava flows (thicker than 125 m) or shallow intrusions (less than 1 km deep), conditions which are common for the Tharsis region. Other possible ejection sites are Elysium or Syrtis Major. In terms

of rare earth elements (REE), *Nakhla* shows a pattern similar to terrestrial basalts.

Nakhlites

Ana-Catalina Plesa
Institute of Planetary Research, German Aerospace Center (DLR), Berlin, Germany

Keywords

SNC meteorites · Rare Earth elements · Cosmic-ray exposure age · Amazonian

Definition

The nakhlites are a subgroup of the SNC meteorites named after the first sample found, the Nakhla meteorite. The nakhlite subgroup contains a total of 12 samples, which are classified as clinopyroxene rich rocks (Udry et al. 2020).

Overview

The nakhlites come most likely from a single impact event, sampling the same region, since they all exhibit cosmic ray exposure ages of 10.6 ± 1 Ma (Eugster et al. 2006). They are enriched in light rare earth elements (LREE) and other highly incompatible elements but are derived from a mantle source strongly depleted in them (Treiman 2005; Nakamura et al. 1982), similar to the MORB-source region and the lunar mare basalt-source region.

The crystallization age of the nakhlites has been estimated to 1.3 Ga (middle Amazonian)

using different isotopic systems (Podosek 1973; Nakamura et al. 1982; Treiman 2005). These clinopyroxenites are thought to have crystallized in thick lava flows (thicker than 125 m) or shallow intrusions (less than 1 km deep), conditions which are common for the Tharsis region (Treiman 1987). Other possible ejection sites are Elysium or Syrtis Major (Treiman 2005; Harvey and Hamilton 2005). Spectral signatures near the detection limit from regions in the eastern Valles Marineris (Juventae, Capri, and Eos chasmata), Terra Tyrrhena, and Syrtis Major Planum (surrounding Nili and Meroe Paterna) have been found consistent with the nakhlitic samples (Hamilton et al. 2003).

Nanoarchaeota

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Nanoarchaeota is a phylum of the DPANN Archaea superphylum that branches closest to the root of the archaeal phylogenetic tree. Cells of *Nanoarchaeum*, the only genus in this phylum, are small coccoids that live as parasites, or possibly as symbionts, of the crenarchaeota *Ignicoccus*. Cells of *Nanoarchaeum* are about 0.4 µm in diameter and replicate only when attached to the surface of *Ignicoccus*. *Nanoarchaeum* is hyperthermophilic, with an optimal growth of about 90 °C. The metabolism of *Nanoarchaeum* is unknown, but its host is an autotroph, growing with H₂ as electron donor and elemental sulfur as electron acceptor. Isolates from *Nanoarchaeum* have been obtained from submarine hydrothermal vents as well as terrestrial hot springs. The genome of *Nanoarchaeum* is only 0.49 Mbp and lacks genes for most known metabolic functions. In addition to the small size of its genome, it is also the most compact of any organism known.

NAP-Astrobio, Brazil

Douglas Galante

Brazilian Center for Research in Energy and Materials, Campinas, Sao Paulo, Brazil

University of Sao Paulo, Sao Paulo, Brazil

Acronyms

NAP-Astrobio: Núcleo de Pesquisa em Astrobiologia (Portuguese); Brazilian Research Unit in Astrobiology

Definition

NAP-Astrobio is a Brazilian virtual network based at the Institute of Astronomy, Geophysics and Atmospheric Sciences of the University of Sao Paulo (USP). It encompasses various Brazilian research centers, such as other institutes of USP and different institutions: the Brazilian Center for Research in Energy and Materials, Federal University of Rio de Janeiro, Federal University of Sao Carlos, Federal University of Santa Catarina, State University of Londrina, and others. The main goals of the network are to foster the interdisciplinary collaboration of researchers, the formation of the next generation of astrobiologists, and the consolidation of the research field in Brazil.

History

NAP-Astrobio was created in 2011 at the University of Sao Paulo (USP) as part of an effort to

organize the Brazilian research community working with different branches of astrobiology. It started with the inauguration of the Astrobiology Laboratory at the Institute of Astronomy, Geophysics and Atmospheric Sciences (IAG) of USP and the organization of the first international school in astrobiology in Brazil, the Sao Paulo Advanced School of Astrobiology Galante et al (2013). At the same year, it was accepted as an international partner of the NASA Astrobiology Institute (NAI) and the European Astrobiology Network Association (EANA).

NASA

Michel Viso
Innovaxiom, Paris, CX, France

Definition

The National Aeronautics and Space Administration (NASA) was established in 1958 as the agency of the US government responsible for civilian space exploration. In 1959, NASA funded its first investigation in what was then called exobiology, a life-detection experiment for a ► [Viking](#) mission to Mars. In 1960, the agency formally established an exobiology program, aimed at advancing this field of study by funding multidisciplinary research projects that other funding sources tended to judge as too

risky. By the 1980s and 1990s, NASA expanded its exobiology program to encompass studies of evolutionary biology and subsequently extended this field to establish “astrobiology” as a program encompassing studies of chemical evolution in interstellar space, the formation and evolution of planets, and the natural history of Earth, in addition to exobiology and evolutionary biology. Today, NASA’s Astrobiology Program addresses these fundamental questions: How does life begin and evolve? Is there life beyond Earth? If so, where should we search for it and how can we detect it? NASA is actively involved in a variety of scientific missions of interest to astrobiology. This includes an ambitious program to explore ► [Mars](#) that has included the Mars Science Laboratory called Curiosity, the land rover Perseverance with its helicopter Ingenuity, and plans for eventual return of samples to the Earth with Mars Sample Return (MSR). To look for habitable planets beyond the solar system, the Kepler Mission was launched in 2006 and the TESS mission in 2018. Possible future missions to characterize exoplanets by direct detection are in the planning stages, as are further missions to solar system targets such as ► [Europa](#), ► [Titan](#), and ► [Enceladus](#).

Natron

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Natronite](#)

Chemical Formula

$\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$

Definition

Natron is a non-marine evaporite. It is a sodium carbonate of the monoclinic crystal system. Its name means “soda” in Latin. Together with thermonatrite and trona, it is one of the minerals which precipitate in soda lakes. These strongly alkaline environments have often been proposed as models for the composition of Hadean oceans. Spectral images from the PanCam instrument onboard of the Mars Exploration Rovers Spirit have identified natron among several hydrated minerals in silica-rich, opaline deposits in the Inner Basin of the Columbia Hills at Gusev Crater, Mars.

Natural Selection

Keywords

Adaptation · Competition · Evolution · Genotype · Heritable traits · Mutation · Phenotype

Definition

Natural ▶ [selection](#) is the process by which heritable traits (present in the ▶ [genotype](#) but reflected in the ▶ [phenotype](#)), raising the likeliness that one organism reproduces successfully, increase their presence in a population. Natural selection requires a population to be intrinsically variable such that different individuals have a different reproductive success. Competition for limited environmental resources privileges the genomes of those producing more progeny, promoting adaptation of the population and, eventually, speciation. Natural selection is a key mechanism of evolution. The development of resistance to antibiotics and pesticides observed in many

microorganisms is an example of natural selection in action.

Overview

The idea of natural selection as the main process behind evolution and adaptation is attributed to Charles R. Darwin (Darwin 1859). Almost simultaneously, Alfred Russell Wallace proposed the mechanism of natural selection as an explanation for biogeographical diversity (Wallace 1858). Although natural selection relies on the inheritance of traits from parents to offspring, a theory of heredity arose only about half a century later (Huxley 1942; Mayr and Provine 1980).

The constructive action of natural selection requires a sufficient amount of heritable individual variation. Variation results from processes that change the genomic composition of populations. Such processes are mutations (arising from errors in the process of genome copying), migration (reproduction between individuals belonging to separated populations or horizontal transfer of genetic elements), and genetic drift (small populations experience stochastic fluctuations that modify gene frequencies). A large number of mutations do not have a direct effect on phenotype (they are neutral) but increase the genomic diversity of populations.

Traits that are positively selected increase their frequency in the population. Due to pleiotropy (occurring when a gene influences multiple phenotypic traits) or genetic linkage, other traits that do not confer any advantage may also become more abundant. This selection of nonadaptive traits might lead to organs that are by-products of natural selection (or spandrels). The reuse of these organs is called exaptation (Gould 2002): feathers evolved to provide insulation but their function was co-opted for display and bird flight. Traits that were once positively selected but are no longer useful usually degenerate into vestigial traits – for example, muscles of the human ear, leg bones in whales, or eyes in the blind mole rat.

Natural selection acts at all levels through the hierarchical organization of biological systems:

The unit of selection can be a molecule, a gene, a cell, a group of individuals, etc. Intragenomic conflict occurs when selection at the level of genes (Dawkins 1976) has deleterious effects on the organism that carries them. The result of natural selection operating at all levels finally determines the fitness of individuals and the success of species in the long run (Okasha 2006). All mechanisms of selection involving environmental features and the structure and behavior of populations are termed ecological selection. This process is different from sexual selection, which refers to intraspecific competition for mates and includes intrasexual competition (usually male to male combat) and intersexual competition (mate choice) (Andersson 1995).

Acronyms

NEO

Definition

A near-Earth object (NEO) is an asteroid or comet with a perihelion distance of less than 1.3 astronomical units (au, the mean Sun–Earth distance). The orbits of NEOs can evolve to intersect that of the Earth; the associated impact hazard is very small but scientifically well-founded. The impact of a NEO with a diameter of just 50 m could cause a major catastrophe. Depending on its orbital parameters, a NEO is categorized as an Amor, Apollo, Aten, or Atira (inner Earth object). As of September 2021, the number of known NEOs is approaching 27,000, of which some 900 have diameters of 1 km or more. The vast majority of the NEOs are asteroids, that is, NEAs. The term “potentially hazardous asteroid” (PHA) is reserved for those with diameters above some 140 m and orbits that bring them within 0.05 au of the Earth’s orbit. PHAs are large enough to survive passage through the Earth’s atmosphere and cause extensive damage on impact. As of September 2021, some 2200 PHAs have been discovered.

Giant planets

Definition

Orbiting the Sun at a mean distance of 30 AU, with a revolution period of almost 165 years, Neptune is the outmost of the ▶ [giant planets](#) and also the smallest. Its diameter is 49,530 km, i.e., 3.9 times the terrestrial value. Still, its mass (17 terrestrial masses) is slightly greater than ▶ [Uranus](#), and its density (1.64 g/cm³) is thus also larger. Both Uranus and Neptune are called “ice giants” because their gaseous envelope consists mostly of water, methane and ammonium compounds, collectively called planetary ices. As all other giant planets, Neptune is surrounded by a system of rings and satellites.

Overview

History of Observations

Neptune was first identified in 1846 by Johannes Galle, who followed the prediction of Urbain Le

Verrier, based on celestial mechanics calculations. The quest for Neptune had started after the discovery of Uranus in 1781, as it was realized that Uranus' orbit was perturbed by another more distant heavy body. John Couch Adam from Cambridge University and Urbain Le Verrier from Paris Observatory came independently to the same conclusion about the position of this distant planet. John Adam, however, did not receive immediate attention from his director. Both predictions were very accurate, as the planet was found within 1° of its predicted position.

Little information was retrieved from visual observations in the following century, as the disk of Neptune is only 2.5 arcsec in diameter on the sky. Atmospheric methane was identified by Rupert Wildt in 1932, and hydrogen, suspected by Gerard Kuiper in 1952 on a theoretical basis, was identified in the 1970s.

Most of our knowledge about Neptune comes from the Voyager 2 spacecraft which encountered the planet in 1989. The Voyager camera revealed an amazing deep blue planet, patched with white cirrus clouds (probably due to methane) and showing a prominent cloud pattern, the "Great Dark Spot," analogous to Jupiter's Great Red Spot (Fig. 1). Voyager determined the temperature structure of Neptune's atmosphere, measured its zonal winds and its helium abundance, and

explored its magnetosphere. Voyager also discovered six new satellites and directly imaged Neptune's rings, which were found to be fully circular and not "arcs," as initially suggested from ground-based observations. Finally, Voyager encountered Neptune's satellite ► [Triton](#) and discovered ► [cryovolcanism](#) at its surface.

The space exploration of Uranus and Neptune has stopped after Voyager, and no mission is presently planned to visit these distant planets. Our knowledge of Uranus and Neptune has benefited from Earth-orbit observations (Hubble Space Telescope, ► [Infrared Space Observatory](#) [ISO], Spitzer) and ground-based telescopic observations from the visible to the millimeter range.

Composition and Structure

The vertical thermal profile of Neptune is very similar to the Uranus profile. As for Uranus, the tropopause, at a pressure of 100 mbar, shows a temperature minimum of about 50 K. Below this tropopause, the ► [tropospheres](#) of the two planets are very similar, while in the ► [stratosphere](#), the thermal profiles strongly differ; Neptune's stratosphere is significantly warmer than the Uranus one. A possible explanation might be the higher stratospheric content of CH_4 and aerosols (hydrocarbon condensates derived from methane photodissociation) in Neptune. Indeed, infrared observations from ISO, Spitzer, Herschel and from the ground have shown that methane is supersaturated in Neptune's atmosphere. The tropopause at the South Pole has been found to be significantly warmer than the rest of the planet, which might be the consequence of its continuous insolation over the last 40 years, as Neptune came to southern summer solstice in 2004. As a consequence, methane, instead of being trapped at the tropopause, is expected to be released into the stratosphere at the South Pole and to spread toward midlatitudes.

The cloud structure of Neptune, as predicted by thermochemical equilibrium models, is very similar to the Uranus one, with a CH_4 cloud at a pressure level of about 1 bar ($T = 80$ K), an H_2S cloud at about a few bars, and deeper clouds of NH_4SH and H_2O between 10 and 100 bar.

Neptune, Fig. 1 The planet Neptune, as observed by Voyager 2 in 1989. (© NASA)

The atmospheric composition of Neptune is similar to that of Uranus with two main differences. First, as mentioned above, stratospheric methane is more abundant, resulting in a more active photochemistry and in greater abundances of hydrocarbons, some of them forming clouds and haze. Second, other stratospheric species have been discovered on Neptune. In 1992, high abundances of CO and HCN were detected in Neptune's stratosphere, by far larger than theoretical predictions. H₂O and CO₂ were detected in 1997 by ISO, and water was later studied by Herschel. A plausible source for this oxygen could be a comet or a flux of ► [micrometeorites](#).

From tropospheric measurements, the C/H ratio was found to be, as in the case of Uranus, enriched by a factor of about 30 with respect to its protosolar value, which is fully consistent with the core accretion model of giant planets' formation. Further evidence is provided by the D/H measured in HD (deuterated molecular hydrogen), first detected by the ISO satellite and more recently by Herschel, which indicates, as for Uranus, an enhancement of D/H with respect to the protosolar value; this enhancement implies the presence of a significant icy core. The helium abundance, measured by Voyager, was found to be in agreement with its protosolar value.

Dynamics and Internal Structure

A striking characteristic of Neptune's atmosphere is its intense dynamical activity. Although more distant from the Sun than Uranus, Neptune shows much more vertical dynamical mixing and a changing climate. The disk of Neptune shows a variety of bright and dark features which vary over time; the white spots, presumably methane ice clouds, may dissipate over timescales of a few days or less. The Great Dark Spot which was identified by Voyager in 1989 had disappeared a few years later when Neptune was observed with the ► [HST](#).

What is the origin of Neptune's dynamical activity? Neptune is known to have a significant source of internal energy. The heat flow, as measured by Voyager from its integrated infrared emission, accounts to 2.6 times the solar energy

absorbed by the planet. The most plausible source for his internal energy is radiative cooling following the heating generated during the accretion phase of the planet. The open question is then to understand why the same process is not active on Uranus, while both planets exhibit very similar physical conditions.

As in the case of Uranus, Neptune's interior, according to theoretical models constrained by the planet's physical parameters, includes a central core of rocks and ices, surrounded by a mixture of ices and by a layer of molecular hydrogen, mixed with helium. At the center, the pressure might reach 8 Mbars and the temperature about 7000 K.

The Magnetosphere of Neptune

The magnetic field of Neptune, discovered and explored by Voyager 2, is, to first approximation, well described by a dipole. As in the case of Uranus, the dipole axis shows a large tilt with respect to the rotation axis (47° in the case of Neptune) and an offset with respect to the planet center (0.5 planetary radii). The dipole representation is valid at distances from 3 to 20 planetary radii. At shorter distances, higher-order multiple moments must be taken into account.

The peculiar configuration of the ► [magnetosphere](#) induces its rapid changes as the planet rotates in the solar wind. At every rotation, i.e., every 16 h, the tilt of the dipole axis, combined with the planetary obliquity of 29°, makes the magnetic pole change from a direction perpendicular to the ► [ecliptic](#) (and thus to the solar wind) to a direction aligned with the Sun-planet axis. As a result, the plasma dynamics are very complex. Auroral regions have been identified at midlatitudes, very different from the auroral ovals of Jupiter and Saturn which appear close to the polar regions.

There is a strong interaction between Neptune's magnetosphere and its largest satellite Triton, which orbits at a distance of 14 planetary radii. Triton is the main source of magnetospheric plasma. Neutral atoms escape Triton's tenuous atmosphere and are ionized in the magnetosphere; the dominant ions are H⁺ and N⁺.

Origin and Migration

Neptune, like the other giant planets, is believed to have formed through the accretion of an icy core of about 10–15 terrestrial masses, and the subsequent collapse of the surrounding gaseous nebula. According to this scenario, however, it is difficult to form such a massive core at the rather large heliocentric distance of Neptune (30 AU). There is also a contradiction in the fact that Neptune, more massive than Uranus, is presently more distant from the Sun. An explanation is proposed by the dynamical model recently developed at Nice Observatory. In this scenario, both Uranus and Neptune would have been formed closer to the Sun (with Neptune possibly closer to the Sun than Uranus) but migrated outward following the dissipation of the ► [protoplanetary disk](#). This migration mechanism would explain, in particular, the structure of the ► [Kuiper Belt](#) and the Late Heavy Bombardment.

Nereid

Therese Encrenaz
LESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Definition

Neptune's satellite Nereid was discovered by Gerard Kuiper in 1949. It orbits in the outer system of ► [Neptune](#), at a distance of 551,300 km (or 222 Neptunian radii), with a high ► [eccentricity](#) ($e = 0.75$) and a high inclination ($i = 27^\circ$). Its diameter is 370 km and its density is 1.5 g/cm^3 ; its surface is dark (with an albedo of 0.12) and heavily cratered. The high ellipticity of Nereid's orbit suggests that, as in the case of ► [Triton](#), Nereid is probably a captured object. The only image taken by Voyager was from a large distance (almost five million kilometers), so very little is known about the surface properties of this satellite.

Neutral Atmosphere

Franck Selsis

CNRS, Laboratoire d'astrophysique de Bordeaux,
Passac, France

Definition

In physics, a neutral atmosphere is an atmosphere consisting of neutral gas, in contrast with the ionosphere. In chemistry, it is an atmosphere which neither oxidizes nor reduces immersed compounds. A planetary atmosphere is rarely chemically neutral because of the photodissociation by stellar UV radiation that produces oxidizing and/or reducing radicals and atoms. An atmosphere dominated by carbon dioxide (CO₂), nitrogen (N₂), and water vapor (H₂O), which many believe to be a good model for the prebiotic Earth's atmosphere, is often referred to as a neutral atmosphere, as it contains neither molecular oxygen (O₂) nor reduced forms of carbon gases, such as methane (CH₄) or carbon monoxide (CO), nor reduced nitrogen species, such as ammonia (NH₃).

Neutral-Neutral Reaction

Ian W. M. Smith

Chemistry Laboratory, University of Cambridge,
Cambridge, UK

Keywords

Chemical kinetics · Interstellar medium · Low temperatures · Rate coefficients

Ian W. M. Smith: deceased.

Definition

A neutral-neutral reaction is a chemical reaction that occurs in collisions between atomic or molecular species that carry no electrical charge. Because of the extremely low gas densities that characterize even the densest regions of the ► [interstellar medium](#), it is only necessary in this environment to consider bimolecular reactions that occur in binary collisions. The crucial properties that are sought in kinetic experiments are the *rate coefficient* and its dependence on temperature, denoted by $k(T)$, and, in cases where two or more sets of products are possible, the *branching ratio*—that is, the fractions of the overall reaction that proceed via different channels. For a bimolecular reaction, say $A + B \rightarrow C + D$, the rate of the loss of A may be written as $-d[A]/dt = k(T)[A][B]$, where the square brackets denoted concentrations, usually expressed in cm⁻³ so that the units of $k(T)$ are cm³ s⁻¹.

History

Chemical kinetics is a relatively mature branch of physical chemistry. The study of neutral-neutral reactions received a boost in the 1960s with the development of methods to study elementary reactions directly and with a burgeoning interest in the chemistry of the terrestrial atmosphere. These experimental methods were adapted fairly easily to the measurement of rate coefficients at temperatures between 200 and 500 K. The results of these studies are reviewed periodically with the evaluated data posted on two websites: <http://www.iupac-kinetic.ch.cam.ac.uk> and <http://jpldataeval.jpl.nasa.gov>. The discovery of the rich chemistry that leads to the presence of molecules in the interstellar medium, particularly in the cold ($T \approx 10$ K) environment of the cold cores of dense, dark, interstellar molecular clouds, has provided another stimulus to laboratory work designed to provide the basic information that serves as input to chemical models of different regions of the interstellar medium. Although the ionization of molecular hydrogen by cosmic rays and subsequent reactions between ions and

neutral species provide much of the driving force for the synthesis of molecular species, there is an increasing appreciation of the potential role of neutral-neutral reactions in this chemistry. This entry focuses on the experimental study of these reactions at temperatures approaching 10 K.

Overview

It is useful to distinguish three kinds of neutral species that can participate in neutral-neutral reactions: (1) *saturated molecules*, in which all the electrons are paired and the atoms are joined by single chemical bonds, examples include H_2 , H_2O , and CH_4 ; (2) *unsaturated molecules*, in which all the electrons are paired but some of the atoms are joined by double or triple bonds, as in HCN , C_2H_2 , and C_2H_4 ; and (3) *free radicals* (hereafter, *radicals*) such as CH and CN , which generally have unpaired electrons and are highly reactive.

Reactions between molecules, for example, $\text{H}_2 + \text{D}_2 \rightarrow 2\text{HD}$, require substantial electronic rearrangement and consequently are characterized by high energy barriers to reaction, the rate coefficients increase strongly with temperature, and at anything but very high temperatures, reaction only occurs in a very small fraction of the collisions between the potential reactants. Reactions between radicals and saturated molecules generally are characterized by barriers in the range $4\text{--}20\text{ kJ mol}^{-1}$, which require temperatures of $500\text{--}2500\text{ K}$ to be overcome. At the low temperatures of dense interstellar clouds (ISCs), the rate coefficients are therefore expected to be extremely small, and these reactions are usually ignored in the chemical models of these astronomical regions. Quite recently, however, laboratory experiments have shown that quantum mechanical tunneling through the barrier is very efficient at temperatures below 200 K for reactions involving the formation of an hydrogen bonded pre-reactive complex along the reaction pathway (Heard 2018; Sims 2013). As a matter of example the rate coefficient of the $\text{OH} + \text{CH}_3\text{OH}$ reaction was found to increase by about two orders of magnitude when the

temperature drops from 200 K to less than 100 K (Heard 2018; Canosa 2019).

Reactions between radicals and unsaturated molecules and between pairs of radicals, which require less electronic rearrangement, frequently do not exhibit energy barriers. For the former case, Smith et al. (2006) have reviewed the kinetic data and recommended two criteria, which might allow one to decide whether the rate coefficient for a particular reaction, for which room temperature kinetic data are available, is (or is not) close to the collision limit at low temperatures. These hypotheses were tested and confirmed in low-temperature measurements (down to 23 K) on the reactions of O atoms with alkenes (Sabbah et al. 2007).

Generally, the rate of reaction between two radicals is determined by their long-range attraction. Such reactions are difficult to study experimentally, but indications are that their rates will generally increase as the temperature is lowered (Hickson and Bergeat 2012; Hickson and Heard 2022).

Basic Methodology

Most rate coefficients for neutral-neutral reactions at and around room temperature have been provided by the application of two experimental techniques (Smith 2011).

The first employs a cylindrical tube (typically 1 m long and 3 cm in diameter). Radical atoms (H , O , N , C) or some small molecular radicals (e.g., OH) are created upstream of the main flow tube in a large excess of “carrier gas” (usually He or Ar). A measured flow of the co-reactant is added to the gas in the main flow tube, and changes in the radical concentration as a result of reaction can be measured by ► [mass spectrometry](#) or a variety of spectroscopic techniques at the downstream end of the flow tube. Because one observes a steady-state concentration of the radicals, a variety of methods can be used to measure the relative concentrations of the radicals that reach the observation point. Knowing the linear flow velocity, the time that elapses between the co-reactant being added and the gas reaching the

observation point can be estimated and hence the rate coefficient for the reaction calculated.

The second method relies on pulsed photolysis, using a laser, of a precursor to create the desired radical in the presence of a much larger known concentration of the neutral co-reactant. The subsequent decay of the radical concentration is observed using a suitable spectroscopic technique. Observing the rate constants for the radical decay in the presence of different concentrations of the co-reactant makes it possible to determine the rate coefficient for the reaction. The pulsed photolysis method has advantages over the flow method in that experiments can be performed over a wide range of total pressures and reactions at the wall of the reactor can be eliminated.

The experimental study of neutral-neutral reactions at low temperatures (<80 K) depends on the application of the CRESU (Cinétique de Reaction en Ecoulement Supersonique Uniforme, for Reaction Kinetics in Uniform Supersonic Flows) technique (Sims et al. 1994; Smith and Rowe 2000; Smith 2006; Potapov et al. 2017; Rowe et al. 2022). Gas (predominantly nonreactive gas such as helium, argon, or nitrogen) is expanded from a gas reservoir through a convergent-divergent Laval nozzle into a large chamber to provide a jet of gas moving at supersonic speed. The density is quite high (typically, $10^{16} - 2 \times 10^{17} \text{ cm}^{-3}$), collisions are therefore frequent, and thermal equilibrium is maintained. The kinetic temperature depends principally on the design of the nozzle. Temperatures as low as 12 K have been achieved with the reservoir at room temperature; lower temperatures can be reached by cooling the reservoir in liquid nitrogen, but that limits what gases can be introduced into the gas flow. The gas in the center of the jet remains uniform in density and temperature for several decimeters, corresponding to around 200 μs when helium is used as a carrier gas and 500–1000 μs for heavier gases such as argon or nitrogen.

The CRESU technique was originally developed for the study of ion-molecule reactions, but during the 1990s, it was adapted (Sims et al. 1994) for the study of neutral-neutral reactions. For ► [ion-molecule](#) reactions, flow methods were adopted: that is, changes in the concentration of

the ionic reactant were measured as a function of either the concentration of the co-reactant or the distance downstream of the mass spectrometer used for observation. For neutral-neutral reactions, pulsed laser photolysis has been deployed to generate radicals, with detection of the changes in their concentration observed by laser-induced ► [fluorescence](#) or by observing chemiluminescence from an electronically excited reaction product. In this way, reactions of the following atomic and molecular radicals – C, Al, Si, B, O, N, S, Cl, F, CN, OH, CH, NH, C_2H , C_2 , C_4H , and CH_2 – have been measured routinely at temperatures down to about 25 K and as low as 6 K in some cases, with a variety of molecular co-reactants (Smith 2006, 2011; Canosa et al. 2008; Potapov et al. 2017; Hickson and Heard 2022).

Key Research Findings

The most important finding from CRESU experiments is the discovery that the rate coefficients for many neutral-neutral reactions, especially those between radicals and unsaturated species and between pairs of radicals, actually *increase* as the temperature is lowered, reaching values close to those estimated by simple collision theory. In detail, however, the form of the variation of $k(T)$ with temperature varies from reaction to reaction. As an example, Fig. 1 shows how the rate coefficients for the reactions of oxygen atoms with alkenes vary with temperature (Sabbah et al. 2007). In this case, the experimental data are well matched by theoretical calculations.

Only limited information has been obtained so far about reactions between pairs of radicals. One of the first studies gave the rate coefficients for the reaction $\text{CN} + \text{O}_2 \rightarrow \text{NCO} + \text{O.O}_2$ has two unpaired electrons, and this reaction proceeds via the transient formation of NCOO radicals, as the unpaired electron on CN and one of the unpaired electrons on O_2 “pair up” to form a chemical bond. The rate coefficient rises monotonically as the temperature is lowered from 298 to 13 K. The values of $k(T)$ agree with theory (Georgievskii and Klippenstein 2005). In an

Neutral-Neutral Reaction, Fig. 1 The points show the experimentally determined values of the rate coefficients for the reactions of $O(^3P)$ atoms with the indicated alkenes at different temperatures, and the *dashed lines* show the results of theoretical calculations using an advanced form

of transition state theory (Georgievskii and Klippenstein 2005). The *solid lines* to the right of the diagram represent Arrhenius expressions that fit the rate coefficients measured between 300 and 700 K

experimental *tour de force*, rate coefficients have been obtained for temperatures down to 38 K for the reaction between the two unstable radicals O atoms and OH (Carty et al. 2006). More recently, a relative technique has been developed to obtain the rate coefficient of the $N(^4S)$ atom reactions with a series of unstable radicals such as CN, CH, OH, C_2 , and C_2N at temperature as low as 54 K using the $N + NO$ reaction as a cornerstone (Hickson and Bergeat 2012; Hickson and Heard 2022).

More information about the rate coefficients for the numerous reactions studied at low

temperatures by the CRESU technique can be obtained from the recent reviews by Smith (2006, 2011), Canosa et al. (2008), Potapov et al. 2017, Cooke and Sims 2019 and the book dedicated to the CRESU technique (Rowe et al. 2022).

Applications

The results from CRESU experiments on neutral-neutral reactions have impacted on work in two other fields. First, it has stimulated a number of

theoretical approaches designed to understand, in detail, the factors that control the rates of reactions under these conditions (e.g., Georgievskii and Klippenstein 2005 and references therein). It is worth pointing out here the considerable interest brought very recently to the $\text{OH} + \text{CH}_3\text{OH}$ reaction by the theoretician community to understand how a reaction with an activation barrier along its reaction pathway could become so efficient at low temperatures (Canosa 2019). Second, although the experiments have not been able to study the neutral-neutral reactions that are likely to be most important in the ► [interstellar medium](#), the experiments have demonstrated that many neutral-neutral reactions remain rapid at very low temperatures and should be included in models of dense interstellar clouds (Smith et al. 2004, 2006).

Recent chemical models of interstellar clouds (Wakelam et al. 2006, 2010, 2015) have been extended in two connected ways: (1) to estimate the errors in the predicted abundances arising from uncertainties in the rate coefficients for reactions included in the model and (2) to show which reactions are likely to have the most influence on the predicted abundances. Such calculations can serve to focus the attention of laboratory astrochemists on the “key” processes in the interstellar medium.

Future Directions

Most of the kinetic experiments on neutral-neutral reactions reach a lowest temperature of ca. 25 K (Potapov et al. 2017; Cooke and Sims 2019). Consequently, there is some uncertainty in predicting the rate coefficients at 10 K for use in models of dense interstellar clouds and pre-stellar cores. The recent development of a new pulsed version of the CRESU technique (Jiménez et al. 2015; Ocaña et al. 2019) based on an aerodynamic chopper opens however the possibility to routinely measure rate coefficients at temperatures as low as 12 K. Further, because of the reduced flows of gases, it could become possible to investigate reactions that involve species that are not readily available (e.g., deuterated molecules) and which can be costly. In addition, attempts are

being made in several laboratories to measure rate coefficients for reactions at much, much lower temperatures (Bell and Softley 2009; Schnell and Meijer 2009; Heazlewood and Softley 2021). These will provide stringent tests of rate theories, which incorporate the quantum mechanical nature of molecular collisions.

Besides the determination of the rate coefficients, obtaining the branching ratios of chemical reactions at interstellar temperatures is essential since these can also be temperature dependent. The field is almost empty but a great deal of new instrumentations including chirped pulse microwave spectroscopy and infrared frequency combs or use of synchrotrons coupled to a CRESU reactor open very promising opportunities in the very near future (Rowe et al. 2022).

Neutron Star

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

A neutron ► [star](#) is a compact object composed mainly of neutrons having a typical mass of 1.4 M_☉ and a typical radius of 10 km. Neutrons are abundantly produced through electron capture by protons in the final gravitational collapse of the dense Fe-core of a massive star. At densities 10¹⁴ g cm^{−3}, the high pressure of the degenerate gas of neutrons resists further collapse, producing a neutron star, provided the mass of the compact object is less than the Oppenheimer-Volkoff limit of 2–3 M_☉; otherwise, the object collapses to a ► [black hole](#). Rapidly rotating neutron stars emit beams of electromagnetic radiation and are known as ► [pulsars](#).

New Horizons

Olivier Witasse
ESA-ESTEC, Noordwijk, The Netherlands

Keywords

Space Mission · NASA · Pluto · Kuiper belt

Definition

NEW HORIZONS is a NASA space mission to explore for the first time the Pluto system and the Kuiper belt. The spacecraft was launched in January 2006. It flew by Jupiter for a gravity boost in February 2007. It conducted a six-month-long reconnaissance flyby study of Pluto and its moons that started in early 2015, which culminated in the Pluto closest approach on July 14, 2015. A flyby of the Kuiper belt object 486958 Arrokoth, also named Ultima Thule, took place on January 1, 2019, at a distance of 43.4 AU from the Sun.

Overview

NEW HORIZONS is a space mission to explore for the first time the Pluto system and the Kuiper belt. It belongs to the category of NASA's New Frontiers Program.

The science payload includes:

- Ralph: Visible and infrared imager/spectrometer
- Alice: Ultraviolet imaging spectrometer

- REX: Radio Science Experiment
- LORRI: Long Range Reconnaissance Imager
- SWAP: Solar Wind Around Pluto
- PEPSSI: Pluto Energetic Particle Spectrometer Science Investigation

The spacecraft was launched on January 19, 2006, from Cape Canaveral. This was the fastest spacecraft ever launched. Thirteen months later, a gravity assist flyby of Jupiter at 32 Jovian radii took place to put the spacecraft into the correct trajectory to reach Pluto in 2015. The Jupiter flyby gave the opportunity to observe the giant planet system. One particular outcome was that most of the Io volcanoes frequently active during the Galileo era continued to be active during the New Horizons flyby.

During its long cruise phase, the spacecraft was put in hibernation, with regular checkouts of the instruments and platform subsystems. The exploration of the Pluto system began 6-month before the closest approach, which occurred on July 14, 2015, at a distance of 12,500 km. Stunning images were returned from this distant world. The data set gathered by the New Horizons instruments revolutionized our knowledge of the Pluto system. Pluto has been surprisingly geologically and climatologically active throughout the past 4+ Gyr and exhibits a remarkably complex range of atmospheric phenomenology and geological expressions. In contrast, the satellite Charon, though also geologically complex, has no detected active surface volatiles, has no detectable atmosphere, and exhibits only ancient terrains.

On January 1, 2019, the New Horizons spacecraft flew close to (486958) 2014 MU69, a cold classical Kuiper Belt object approximately 30 kilometers in diameter. Such objects have never been substantially heated by the Sun and are therefore well preserved since their formation. MU69 is a bilobed contact binary with a flattened shape, discrete geological units, and noticeable albedo heterogeneity. No evidence for satellites, rings or other dust structures, a gas coma, or solar wind interactions was

detected. MU69's origin appears consistent with pebble cloud collapse followed by a low-velocity merger of its two lobes.

The trajectory of New Horizons in the solar system allows to acquire also a unique data set on the solar wind variability in the heliosphere.

Nice Model

Alessandro Morbidelli¹ and Sean N. Raymond²

¹Observatoire de la Cote d'Azur, Nice, France

²Laboratoire d'Astrophysique de Bordeaux, CNRS, Universite de Bordeaux, Bordeaux, France

Definition

The so-called “Nice model” describes dynamical evolution of the outer Solar System since the time when the gas was removed from the ► [protoplanetary disk](#). In this model, the ► [giant planets](#) underwent a dynamical instability which played a major role in shaping the present-day Solar System. This instability could have happened several 100 million years after the planets formed. The Nice model can explain several observations in the Solar System, including the orbits of the giant planets, the existence and the orbital structure of several small body populations (e.g., Jupiter’s Trojans), and the ► [late heavy bombardment](#).

Overview

There are two versions of the Nice model.

The first one (*Nice I*) was presented in 2005 in a trilogy of papers published on the *Journal Nature*. In that version of the model, the assumption was made that the giant planets formed in a more compact configuration than their current one, with a ratio between the orbital periods of Saturn and Jupiter smaller than 2 (when the period ratio is exactly 2, the planets are said to be in 2:1 ► [mean motion resonance](#); the current period ratio is almost 2.5). The model also assumes that exterior to Neptune there was a massive primordial disk of small bodies (planetesimals), totaling perhaps 50 Earth masses. The long-term evolution simulated on computers proceeded as follows. Over time, Neptune’s gravity perturbed the orbits of nearby planetesimals onto crossing orbits and

led to scattering events. Due to its relatively small mass, Neptune preferentially scattered planetesimals inward. Due to a combination of their masses and orbits, Uranus and Saturn also preferentially scattered planetesimals inward, but Jupiter’s very large mass enabled it to preferentially scatter planetesimals outward (onto hyperbolic orbits and thus out of the solar system). The back-reaction of these scattering events caused the planetary system to slowly spread out, with Jupiter migrating inward and Neptune, Uranus, and Saturn moving outward. After a long delay, the system’s spreading caused Jupiter and Saturn to cross that 2:1 resonance, leading to an impulsive increase in the orbital eccentricities of those planets. This led to a rapid destabilization of the orbits of Uranus and Neptune and also of the remaining planetesimals in the outer system. Jupiter dynamically ejected the vast majority of these small cometary bodies from the system, but a small fraction collided with the terrestrial planets in an event known as the “Late Heavy Bombardment” (LHB). A contribution (possibly a dominant one) to the LHB also came from asteroids ejected from the asteroid belt during the migration of Jupiter and the excitation of the eccentricity of its orbit.

The second version was presented in 2007 and was subsequently refined in a series of papers. The main reason for promoting a new version of the model is that the initial orbits of the giant planets assumed in the 2005 model do not seem to be supported by hydrodynamical simulations of the evolution of said planets in the disk of gas in which they formed. The hydrodynamical simulations show that the giant planets migrate in the disk of gas relative to each other until they reach a fully resonant configuration. Saturn is typically locked in the 3:2 resonance with Jupiter (i.e., the period ratio is 3/2), while Neptune and Uranus can occupy a series of resonances with Saturn and with each other: 3:2, 4:3, 5:4, etc. This multi-resonant configuration is also consistent with the end-state of the Grand Tack Model (see ► [“Planet Formation”](#)). The new version of the Nice model (known as “*Nice II*”) uses these multiresonant configurations as initial conditions for the

planetary orbits. In this way, there are no arbitrary and ad-hoc assumptions on the initial orbits of the planets, unlike in *Nice I*.

Like in *Nice I*, the planets are assumed to be surrounded by a disk of planetesimals, extended from a few Astronomical Units (AU) beyond the orbit of Neptune up to about 30–35 AU. Computer simulations show that the distant interactions between the planets and the planetesimals slowly perturb the planetary orbits. Eventually, after a time that can be as large as a billion years, one planet is extracted from a resonance. When this happens, the planetary system immediately becomes unstable. The planetary orbits, in fact, are so close to each other that they can be stable only as long as the planets are all in resonance with each other. A good analogy to this situation is the Sun-Neptune-Pluto system. The system is stable because Pluto is in the 3/2 resonance with Neptune. But if Pluto were extracted from the resonance, its orbit would immediately become unstable.

Once the system of giant planets is destabilized, the subsequent evolution can follow one of three possible general trends. A first possibility is that Saturn and Jupiter have close encounters with each other. This in general leads to the ejection of all planets except Jupiter, who survives on a very eccentric orbit. This obviously did not happen in reality in our Solar System, but the final orbit of Jupiter in these cases is consistent with those of many giant planets that are observed around other stars. A second possibility is that Jupiter does not encounter any other planet. Only Saturn, Uranus, and Neptune are involved in mutual close encounters. We can exclude that also this possibility happened in the real Solar System. In fact, in this case, the ratio of orbital periods between Saturn and Jupiter would have increased slowly, on a timescale of millions of years. This would have destabilized the orbits of the terrestrial planets and would have sculpted the asteroid belt into an orbital structure very different from the one we observe today. The third possibility, the only one that is consistent with the current structure of the Solar System, is that Jupiter had close encounters with either Uranus, or

Neptune, or an additional planet of similar mass (eventually ejected to interstellar space). In particular, Saturn injects the Uranus-mass planet toward the inner solar system and Jupiter ejects it further out. In this process, the period ratio between Jupiter and Saturn “jumps” impulsively. This kind of evolution (dubbed “*Jumping Jupiter*”) preserves the stability of the terrestrial planets, does not produce weird orbital structures in the asteroid belt and also best reproduces the current orbits of the giant planets in terms of mutual orbital spacing, eccentricities, and inclinations.

Like in the case of the *Nice I* model, during the planet instability phase, Uranus and Neptune are eventually scattered outward and disperse the planetesimal disk. The interaction between the planets and the dispersing disk eventually parks the former on quasi-circular and quasi-coplanar orbits similar to the current ones. The dispersal of the trans-Neptunian disk and the partial destabilization of the asteroid belt trigger a heavy bombardment on the terrestrial planets.

Overall, the Nice model can explain many attributes of the Solar System. It explains the current orbits of the giant planets, in terms of mutual spacing and eccentricity and inclination excitation. In fact, the Nice II model is the bridge linking the multiresonant orbits that the giant planets should have had when they emerged from the gas-disk phase to the current orbits. Other Solar System characteristics that the model explains include: the timing of the LHB, the orbital distribution of Jupiter’s Trojan population, the characteristics of the irregular satellites of the giant planets, and many of the dynamical properties of the ► [Kuiper belt](#).

Keywords

Anaerobic respiration · Denitrification · DNRA · Nitrogen cycling · Oxygen minimum zones · Great Oxidation Event

Synonyms

Autotrophic denitrification; Dissimilatory nitrate reduction to ammonium (DNRA); Heterotrophic denitrification

Acronyms

DNRA

Definition

Nitrate reduction refers to biological processes in which the most oxidized form of nitrogen, nitrate (NO_3^-), serves as an electron acceptor during chemotrophy, either heterotrophically (with organic carbon) or autotrophically (e.g., with reduced sulfur compounds).

Overview

Nitrate (NO_3^-) is a common form of dissolved inorganic nitrogen that builds up in modern

aqueous systems. Nitrate is generally produced by the oxidation of ammonium (NH_4^+) and provides an important source of the nutrient nitrogen for life. As such, nitrate forms a key component of the global nitrogen cycle (e.g., see Galloway 2014). Nitrate reduction proceeds via a variety of pathways, most of which are mediated by microorganisms. In particular, nitrate can serve as the terminal electron acceptor during the anaerobic respiration of organic carbon. This process, termed *heterotrophic denitrification*, is confined to environments where oxygen is depleted. On the modern Earth, this includes marine sediments, particularly continental margins and hemipelagic sediments, and oxygen minimum zones (OMZs). The canonical heterotrophic denitrification pathway has been well described and generally follows the enzymatic reduction of nitrate to nitrite, nitric oxide, nitrous oxide, and finally to gaseous N_2 (Zumft and Korer 1997). Nitrous oxide (N_2O) can accumulate as an intermediate during denitrification, providing a source of this potent greenhouse gas. The capacity for heterotrophic denitrification is widespread among microorganisms, mainly within the *Proteobacteria* (Zumft 1997).

Nitrate reduction can also be coupled to the oxidation of reduced sulfur compounds during *autotrophic denitrification*, which can produce either N_2 or ammonium. The capacity to reduce nitrate or nitrite to ammonium (*DNRA*) is spread across a range of anaerobic and aerobic genera (Tiedje 1988), although DNRA has been reported mainly in anoxic sediments and in sediments with substantial free sulfide, where nitrification and heterotrophic denitrification are inhibited. Organisms such as *Thioploca* and *Thiomargarita* commonly perform DNRA in sediments underlying major OMZs, such as off the coast of Namibia (Fossing et al. 1995). These organisms accumulate the elemental sulfur products of sulfide oxidation and can concentrate nitrate to >100 mM levels in large vacuoles within their cells. As such, *Thiomargarita* is currently the largest known bacteria and is visible to the naked eye (Schulz et al. 1999). Notably, biologically available nitrogen

is removed from the biosphere through denitrification or the related pathway of anaerobic ammonium oxidation (*anammox*; reduction of nitrite to N_2 with ammonium), while DNRA retains it. Recent studies suggest that the balance between N_2 and NH_4^+ production during nitrate reduction generally depends on environmental parameters such as organic carbon, nitrite, and nitrate availability (Kraft et al. 2014). Nitrate reduction coupled to methane oxidation has also been recently described in freshwater settings (Nordi and Thamdrup 2014), but the importance of this process in global nitrogen and methane budgets remains unclear.

Nitrate was unlikely to have been widely available in the anoxic environments that characterized the early Earth, since the oxidation of ammonium (*nitrification*) generally requires molecular oxygen. Nitrogen isotopes preserved in the sedimentary rock record are consistent with N cycling processes that utilized oxidized nitrogen species, including denitrification and anammox, back to 2.4 billion years ago (Kipp et al. 2018) and possibly to 2.7 billion years ago (Godfrey and Falkowski 2009), but interpretations of these data are non-unique. Regardless, nitrate would presumably have become widespread in the oxygenated surface oceans that developed immediately following Earth's Great Oxidation Event (GOE), from ~ 2.3 billion years ago (Farquhar et al. 2014; Zerkle et al. 2017). Increased availability of nitrate after the GOE, coupled with widespread ferruginous bottom waters, could have led to high rates of denitrification and enhanced losses of fixed N. Thus nitrogen limitation has been implicated in hindering biological evolution, as well as the continued oxygenation of Earth's surface environments, throughout much of the Proterozoic (Fennel et al. 2005).

Nitrates on Mars

Daniela Tirsch¹ and Alessandro Airo²

¹German Aerospace Center DLR, Institute of Planetary Research, Berlin, Germany

²Institut für Geologische Wissenschaften Tektonik und Sedimentäre Geologie, Freie Universität Berlin, Fachbereich Geowissenschaften, Berlin, Germany

Definition

Nitrates are salts of the nitric acid (HNO₃). It has been estimated that one quarter of the initial Martian atmospheric molecular nitrogen today is fixed in the form of nitrates in the soil. A possible formation process of these nitrates is the dissociation of the atmospheric molecular nitrogen through shock heating caused by impacts or through photochemical reactions (Smith et al. 2014). Nitrates are highly soluble in water, hence nitrates entrained in the Martian ► [cryosphere](#) may contribute to the generation of brines near the surface. Because nitrates are a fundamental source of nitrogen for life on Earth, the detection of nitrates on Mars is an important parameter for the assessment of potential habitable environments. Recent analyses of “Rocknest” sand samples at Gale crater by the NASA rover “Curiosity” tentatively indicate the presence of nitrates.

Nitrification

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Madrid, Spain

Definition

Nitrification is an oxidative biological process that converts ammonia into nitrate. The whole process is composed of two different steps which are performed by different microorganisms: ammonia to nitrite and nitrite to nitrate. The first step is performed by organisms of two domains: ► [Bacteria](#) (genera *Nitrosomonas* and *Nitrosococcus*) and ► [Archaea](#) (Crenarchaeota phylum). The second step is driven by Bacteria (gen. *Nitrobacter*). Nitrification is an important part of the nitrogen cycle.

Keywords

Miller-Urey experiment · Prebiotic chemistry

Synonyms

[Organic cyanide](#)

Definition

According to the recommendations of the IUPAC Nomenclature of Organic Chemistry, *nitriles* are

organic compounds containing the group $\text{—C}\equiv\text{N}$ (substitutive nomenclature scheme). Alternatively, the same compounds are called *cyanides* in the radicofunctional nomenclature scheme.

History

The term *nitrile* was first used by Fehling in 1844 in his work on benzonitrile.

Overview

The relevance of nitriles in astrobiology and in the study of the origin of life in our planet is related to their alleged role in ► [prebiotic chemistry](#) that preceded the appearance of life on Earth. Two points are in favor of this suggestion. First, there are efficient reaction schemes that start from simple nitriles, such as $\text{H—C}\equiv\text{N}$, and lead to the synthesis of ► [amino acids](#) and nucleic bases, which are amongst the most important building blocks of a living cell. Second, simple nitriles, such as $\text{CH}_3\text{—C}\equiv\text{N}$ and $\text{C}_2\text{H}_5\text{—C}\equiv\text{N}$, and more exotic ones, such as cyanopolyynes from $\text{HCC—C}\equiv\text{N}$ to $\text{HC}_{10}\text{—C}\equiv\text{N}$, have been observed in a variety of extraterrestrial environments (Ehrenfreund et al. 2002), thus suggesting that several gas-phase reactions easily produce them from simple parent species widely spread in the Universe (Balucani 2009). ► [Hydrogen cyanide](#), $\text{H—C}\equiv\text{N}$, can be considered the first member of the nitrile homologous series, but its properties are quite different compared to higher nitriles because of the ability to produce CN— ion. HCN has been identified in numerous extraterrestrial locations, ranging from ► [interstellar clouds](#) to planetary atmospheres and ► [comets](#). Exceptionally widespread has been the observation of the CN radical, which was among the first molecular species ever observed in the ► [interstellar medium](#). The prebiotic character of hydrogen cyanide has been clearly assessed (Delaye and Lazcano 2005; Eschenmoser 2007; Ehrenfreund et al. 2002). In aqueous solution containing imines (or aldehydes and ammonia), it leads to the synthesis of alpha amino acids following the

► **Strecker synthesis** scheme (this is the accepted explanation for the formation of amino acids in the Miller-Urey experiment). Also, adenine and guanine, important RNA and DNA bases, can be formed by the polymerization of HCN in water. Cyanoacetylene ($\text{HCC}-\text{C} \equiv \text{N}$, identified in interstellar clouds and in the atmosphere of ► **Titan**) can be involved in reactions producing cytosine and uracil in the aqueous phase (Ehrenfreund et al. 2002). Aqueous solutions of acetonitrile ($\text{CH}_3-\text{C} \equiv \text{N}$) and propionitrile ($\text{C}_2\text{H}_5-\text{C} \equiv \text{N}$), under the action of ionizing radiations, lead to the formation of oligomers, which upon hydrolysis release amino acids (Draganic et al. 1977). Finally, ionizing radiation produces amino acid precursors in icy environments that contain CH_3CN (Hudson et al. 2008).

Definition

Nitrogen (elemental symbol: N) is the seventh chemical element in the periodic table. Nitrogen nuclei contain seven protons, and most commonly seven neutrons (the most abundant isotope, ^{14}N , has a monoisotopic mass of 14.00674 amu; the second most important nonradiogenic isotope, ^{15}N , has eight neutrons). It is the seventh most abundant element in the universe, but the fourth most abundant element in biochemical systems. It is the most abundant component (in the form

dinitrogen, N₂) of the atmospheres of the Earth (78.08% by volume) and of Saturn's moon Titan, and a significant component of the atmospheres of Mars and Venus. It is also common in the form of ammonia (NH₃) in comets and the gas giant planets of the solar system.

History

The name nitrogen derives from the Latin *nitrogenium*, which is itself derived from *nitrum*, from the Greek *nitron*, meaning “saltpeter,” and *genes* meaning “forming.” Nitrogen is usually considered to have been discovered by Daniel Rutherford in 1772.

Overview

Elemental nitrogen is believed to be primarily synthesized by stellar nucleosynthesis during the CNO cycle via the following set of reactions (γ : gamma photon; ν_e : electron neutrino):

When the cycle is run to equilibrium, ¹⁴N becomes the most abundant nucleus, regardless of the initial composition.

The nitrogen atom has the electron configuration 1s²2s²2p³; it would need to add three electrons to achieve the neon noble gas stable electron configuration. This can be achieved, for example, by the addition of three hydrogen atoms to yield the ammonia molecule (NH₃). In addition to this molecular form, nitrogen is also found in a variety of oxidation states from −3 to +5 as a component

Nitrogen, Table 1 Some commonly encountered small nitrogen-containing molecules

Compound	Formula	Oxidation state
Ammonia/nitride/cyanide	NH ₃ /N ^{3−} /CN [−]	−3
Hydrazine	H ₂ N-NH ₂	−2
Hydroxylamine	HONH ₂	−1
Dinitrogen	N ₂	0
Dinitrogen monoxide	N ₂ O	+1
Nitrogen monoxide	NO	+2
Nitrous acid	HNO ₂	+3
Nitrogen dioxide	NO ₂	+4
Nitric acid	HNO ₃	+5

Note: Molecules are found in all of the oxidation states from −3 to +5

of simple molecular compounds, most of which are gases at STP, though many of them readily dissolve in water (Table 1). The peculiar chemical reactivity of most nitrogen-containing compounds is very often connected to the presence of a lone, nonbonding electron pair on the nitrogen atoms.

Nitrogen is extremely important in biological systems, being a major component of common biochemical compounds including amino acids and proteins, the nitrogenous bases found in nucleic acids, and various other compounds including the alkaloids and biopolymers such as chitin. Indeed, biological tissue commonly contains as much as 14 wt% nitrogen, making it the fourth most abundant biologically important element. This represents a many thousand-fold enrichment relative to its cosmic and solar abundances.

One possible reason for this biological enrichment, in addition to cosmic abundance and prebiotic reactivity arguments, is that nitrogen in its reduced form can form C–N–C bonds, which offer novel geometric arrangements for molecules, and useful chemical reactivity. For example, organic compounds containing reduced nitrogen provide nucleophilic amine groups, which offer the possibility of simple addition chemistry in water, due to the relatively high basicity of amines relative to the corresponding oxygen-containing analogues. For these and other

reasons, it has been argued that searches for extra-terrestrial life should “follow the nitrogen” (Capone et al. 2006), that is, that reduced nitrogen may offer a signature of biological activity – although the rich H/C/N-based chemistry on Titan offers an abiotic counterexample.

The vast majority of the biologically important N-containing molecules contain nitrogen in the -3 oxidation state, while the most abundant form of nitrogen found on Earth is in the 0-oxidation state (Earth’s largest N reservoir is believed to be in the atmosphere as N_2), highlighting the importance of nitrogen reduction and the biological nitrogen cycle. In spite of the variety of nitrogen-containing molecular compounds, and of the variety of nitrogen oxidation states therein, it seems likely, as proposed initially by Mendeleev, that the majority of the Earth’s nitrogen was delivered in its -3 oxidation state, principally in the form of nitrides and ammonia (Hutsemekers et al. 2009). However, it also seems likely that nitrogen was fairly rapidly equilibrated and removed from mineral reservoirs: while nitrides are stable forms under the low T and low P conditions of the early solar systems, they are much lesser under the high T and P conditions of rocky planets’ mantles and cores. Nitrogen was likely rapidly outgassed from the early mantle, and NH_3 was removed from atmospheric reservoirs via photolysis. Studies of the solubility of nitrogen in magmatic melts (Miyazaki et al. 2004), and studies of the photochemical stability of ammonia (Ferris and Nicodem 1972) also support this notion, thus the general chemical stability of ► [dinitrogen](#) makes it a likely reservoir where kinetic effects dominate environmental nitrogen cycling.

Nitrogen occurs naturally in many terrestrial minerals, such as potassium nitrate, sodium nitrate, and ammonium chloride; however these are fairly uncommon since they are extremely water soluble.

In interstellar molecular clouds, nitrogen is thought to be mostly present as dinitrogen (N_2), whose presence is deduced from observations of N_2H^+ . Other nitrogen compounds, including ammonia, various nitriles, and cyanopolynes are also present (see “► [Molecules in Space](#)”).

[Biogeochemical cycle of nitrogen](#)

Definition

The circulation of the various chemical forms of nitrogen among the atmosphere and aquatic and terrestrial ecosystems. The cycle essentially consists of the transformation, through several not sequential steps, of the organic nitrogen forming

part of the soil, plant, and animal debris into mineral and gaseous forms and viceversa, with the key participation of diverse bacteria and fungi.

History

It was not until the end of nineteenth century that the transformation of nitrogen compounds that occurred in the soil was related to microbial activities. T. Schloesing and A. Muntz discovered the process of nitrification in 1877. U. Gayon and G. Dupetit in 1886 were the first reporting denitrifying bacteria, whereas M. Hellriegel and M. Wilfarth in 1888 were also pioneers reporting the biological character of nitrogen fixation. The anammox (anaerobic ammonia oxidation) process was first observed in a pilot plant for the treatment of wastewater and reported in 1995 by the group of J. Kuenen. Anthropogenic activities, especially since the mid-twentieth century, have dramatically altered the nitrogen cycle, particularly by enhancing the amounts of reactive nitrogen circulating at regional and global scales, and the eventual accumulation of reactive nitrogen forms in certain ecological reservoirs (Galloway et al. 2004; Erisman et al. 2015).

Overview

The biogeochemical cycle of nitrogen is especially complex due to this element forming stable compounds in several valence states (from 5^+ to 3^-). Besides plants, many soil and water microorganisms are able to use nitrogen as a nutrient in mineral form, mainly as nitrate or ammonia coming from the mineralization of the organic matter. The mineralization begins with the transformation of the organic nitrogen (i.e., amino acids, nucleic acids) into ammonia. This step of the cycle is known as ammonification in which many bacteria, most of them heterotrophic, as well as some fungi participate. The resulting ammonia is either used by plants and bacteria (transitory immobilization) or oxidized to nitrate. This process called nitrification occurs in two stages, first from ammonia to nitrite and afterward

from nitrite to nitrate. Both steps are carried out by chemolithoautotrophs such as *Nitrosomonas* and *Nitrobacter* species, respectively, although there is evidence of the involvement of some heterotrophs. The final compounds can also be transitorily immobilized being assimilated by bacteria or absorbed by plant roots. Part of the nitrate produced is, however, reduced to molecular nitrogen through various steps in the denitrification process (NO_2^- , NO , N_2O , N_2). Denitrification is a form of respiration, and the microorganisms involved are either strict anaerobes or facultative anaerobes growing in the absence of oxygen. Denitrification has been well studied in *Paracoccus denitrificans* and some *Pseudomonas* species as well as in *Bradyrhizobium japonicum*, which is a nitrogen fixer but also a denitrifying bacterium. Nitrogen fixation, the reduction of molecular nitrogen to ammonia carried out by nitrogen fixers, free living or in symbiosis with plants, can recover the dinitrogen evolved by denitrification, thereby closing the cycle. The anammox process is the oxidation of ammonia to molecular nitrogen in anaerobiosis using nitrite as an electron acceptor, and that mainly occurs in wastewater treatment. All steps of the nitrogen cycle play an important role in the fertility of soil, either increasing the available nitrogen for plants or causing its loss as in the case of denitrification. Some microbial activities like denitrification also release to the atmosphere nitrogen oxides involved in climatic change, acid rain, and integrity of the ozone layer.

Synonyms

[Atmospheric dinitrogen fixation](#)

Definition

The term nitrogen fixation involves the combination of molecular nitrogen (dinitrogen, N_2) with oxygen or hydrogen to give nitrogen oxides (NO , N_2O) or ammonia (NH_3), respectively. Molecular nitrogen is the main component of the atmosphere, albeit it is considered an unreactive form and cannot be directly used by most living organisms, which generally can only use oxidized or reduced forms of nitrogen. In other words, nitrogen fixation is the conversion of molecular nitrogen into reactive nitrogen forms.

History

Although Malpighi had reported already in 1679 the presence of “small tumors” in the roots of legumes, it was not until 1888 that M. Hellriegel and M. Wilfarth recognized that nodules in

legume roots were responsible for the conversion of atmospheric nitrogen to ammonia. Also in 1888, M. Beijerinck was the first to isolate bacteria from several legume root nodules and confirmed their involvement in nitrogen fixation and plant nitrogen nutrition. This same author discovered in 1901 the ability of *Azotobacter* and *Clostridium* to fix nitrogen in free-living conditions. In the early 1900s, F. Haber invented and C. Bosch developed the Haber-Bosch process for the catalytic synthesis of ammonia from dihydrogen and dinitrogen under conditions of high temperature and pressure, so-called industrial nitrogen fixation. In the twenty-first century, new approaches involving electrocatalytic reduction of dinitrogen for a more sustainable industrial synthesis of ammonia are being explored (Martin et al. 2019).

Overview

Dinitrogen can be oxidized or reduced by physic-chemical processes, forming N oxides produced by electrical discharges or by combustion of fossil fuels, or the reduced-form ammonia produced by the industrial Haber-Bosch process. It can also be reduced to ammonia by bacteria free-living or in symbiosis with plants, through a process known as biological nitrogen fixation (BNF). The ammonia produced is either assimilated by free-living bacteria, or in the case of symbiotic fixation, transferred directly to the host plant. Nitrogen fixation may globally account for 250 million Tn per year, roughly 50% of this quantity corresponds to biological processes. Most of the remaining 50% originates from H-B industrial production of fertilizers for agriculture. BNF is a highly energy-consuming and oxygen-sensitive process, and is a capacity restricted to prokaryotic organisms, bacteria and archaea, so-called diazotrophs or nitrogen fixers. The reduction of N_2 is catalyzed by the enzyme nitrogenase, constituted by two metalloproteins, ferroprotein and molybdoferroprotein, well conserved among all nitrogen fixers. The reaction proceeds according to the following equation:

The nitrogenase shows a wide range of activity on molecules containing triple bonds, which has led to think on its possible detoxifying role in the early-earth environment, and has provided an easy detection and measurement method of this activity based on the reduction of acetylene to ethylene. Besides ammonia, H_2 is released as a byproduct of the nitrogenase activity, which causes a loss of efficiency in the process. BNF has great importance from ecological/environmental and economical points of view. It occurs in all habitats, terrestrial and aquatic ecosystems, and balances the biogeochemical nitrogen cycle by retrieving from the atmosphere, the nitrogen lost by denitrification. BNF carried out by free-living bacteria has a limited agricultural significance due to its high energetic requirements, in contrast to BNF by plant symbiotic bacteria, where the microorganisms use carbon and energy sources from plant photosynthesis. Among plant species which are able to fix nitrogen are the legumes, of great importance for animal feeding and human nutrition. Legumes associate with nitrogen-fixing bacteria of diverse genera and species collectively known as Rhizobia. Exploitation of this capacity, achieved through bacterial selection and inoculation of agriculturally important species, is a practice that greatly contributes to agroecosystem sustainability (Olivares et al. 2013).

Nitrogen cycle (biological) · Isotope anomaly · Isotope fractionation · Organic formation · Solar composition

Definition

Nitrogen has two stable isotopes, nitrogen-14 and nitrogen-15. The abundance ratios of the two isotopes among geological samples, both extraterrestrial and terrestrial, exhibit wide variations, despite the first-order expectation of its stable

nature. This expectation derives from the absence of important sinks or sources of these nuclides by any known nuclear reactions that may naturally occur, apart from their nucleosynthesis in several kinds of stellar environments. Nitrogen is one of the most important elements in organic matter preserved in geological samples. The isotopic variations of nitrogen may provide important clues to decipher the formation processes for these samples.

Overview

The abundance ratios of nitrogen-14 and nitrogen-15 among extraterrestrial samples exhibit more than a factor of 2 variation, the largest among all elements except for hydrogen. Interesting isotopic variations are also observed among nitrogen from various terrestrial samples that represent the compositions of different reservoirs in the Earth, such as the nitrogen in the mantle, in the atmosphere, or in the biosphere present and past. Although the exact reasons for the variations are yet unresolved, growing evidence suggests that a better understanding of the variations may have important astrobiological implications in the evolutions both of the early solar system and of the Earth.

Basic Methodology

The nitrogen isotopic ratios ($R = {}^{15}\text{N}/{}^{14}\text{N}$) among geological samples are normally expressed in the δ -notation, that is, by the difference of the ratio in per mil units relative to the ratio of the reference standard; $\delta {}^{15}\text{N} \equiv (R/R_{\text{std}} - 1) \times 1000$. The international reference standard for nitrogen is the terrestrial atmosphere with R_{std} of 3.676×10^{-3} .

Key Research Findings

Nitrogen Isotopes in the Early Solar System

Nitrogen is abundant, typically at 0.1–1.0% levels, in primitive planetary materials, that is, chondritic meteorites, interplanetary dust

particles, and cometary dust. Their isotopic compositions can be regarded as representing those of the building blocks forming rocky planets in the solar system. The nitrogen isotopic ratios among meteorites of different chemical groups, which likely correspond to those from different asteroids, show widely different $\delta {}^{15}\text{N}$ values, ranging from -95 to $+1122\text{‰}$ among bulk samples (Fig. 1). Interestingly, only a limited number of meteorites known so far show $\delta {}^{15}\text{N}$ values with near terrestrial compositions ($\sim 0\text{‰}$). This may either suggest that (1) the Earth has sampled kinds of building blocks different from the known meteoritic populations; (2) the Earth was produced from melanges of several different kinds of building blocks; or (3) the terrestrial composition was altered by planetary processes after the accretion. A good example for the third possibility is seen on Mars and Titan, where the atmosphere is highly enriched in ${}^{15}\text{N}$ ($\delta {}^{15}\text{N} \sim +750\text{‰}$ (Mars) or $+490\text{‰}$ (Titan); see references in Marty et al.

Nitrogen Isotopes, Fig. 1 Nitrogen isotopic compositions among chondrites and interplanetary dust particles (IDPs) compared with the proto-solar composition (Respective data are taken from literatures referenced by Busemann et al. (2006), Floss et al. (2004), Hashizume et al. (2000), Marty et al. (2011), and Nakamura-Messenger et al. (2006). Note that the values for the meteorites and IDPs are the “bulk” compositions, somewhat rounded by mixture of several isotopically distinct components, including the terrestrial contaminations. Within respective chondrites, numbers of subcomponents, besides the nitrogen from the identified presolar grains (Zinner 2005), are observed exhibiting a wide $\delta {}^{15}\text{N}$ range from -230‰ to $+3200\text{‰}$)

2011). This is due to the preferential escape of the lighter isotope from the planetary atmospheres, although whether such a process may have occurred on larger-mass planets like the Earth is still an issue.

A couple of possibilities are proposed to explain the variations among the extraterrestrial samples. (1) Isotopic variations are caused by heterogeneous distribution of “exotic” nitrogen-bearing compounds among the planetary materials, which reflect the isotopic compositions unique to the source reservoirs for each compound, such as stars with different nucleosynthetic productions. (2) Large isotopic fractionation occurred in the formation process of the nitrogen-bearing compounds. Although several kinds of presolar grains (diamonds, graphite, silicon carbides, or silicon nitrides) are identified so far among the primitive meteorites (Zinner 2005), exhibiting strikingly anomalous nitrogen isotopic ratios, their abundances are generally too low to explain the overall isotopic variations observed among the bulk meteorites. The dominant fraction of nitrogen in primitive planetary materials is in the form of highly polymerized organic matter. By recent isotope studies of extraterrestrial organic matter using high space-resolution ion microprobes, submicron-sized organic grains with highly positive $\delta^{15}\text{N}$ values, up to +3200‰, are identified among primitive meteorites (Busemann et al. 2006; Nakamura-Messenger et al. 2006), interplanetary dust particles (Floss et al. 2004), and cometary dust (Stadermann et al. 2008). Some of such grains are enriched also in deuterium, which is generally considered to suggest that the organic formation occurred at low temperature, for example, in the molecular cloud or in the outer region of the proto-solar nebula. However, interestingly, not all of the grains are associated with the D enrichment, possibly suggesting the provenance of such ^{15}N -rich organic grains from several different sources (Marty et al., 2011). Part of the reasons for the deviation between the ^{15}N and D enrichments could be due to the presence of important isotope fractionation processes peculiar to the element, for instance the one produced by photochemical

processing of nitrogen reservoirs within the solar nebula (Chakraborty et al. 2014).

The nitrogen isotopic composition of the Sun plays a pivotal role in constructing the framework. The proto-solar nebula corresponds to the ultimate source material of all solid compounds generated in the Solar System. Nitrogen isotope studies of the solar wind implanted in lunar regolith samples (Hashizume et al. 2000), of Jupiter’s atmosphere (the nebular gas trapped by the giant planet; Abbas et al. 2004; Wong et al. 2004), of a refractory mineral in meteorites considered to be in equilibrium with the nebular gas (Meibom et al. 2007), and of the contemporary solar wind collected by a solar-circling spacecraft (Marty et al. 2011), all arrived to the same conclusion that the solar composition has much lower $^{15}\text{N}/^{14}\text{N}$ ratio than any planetary materials. The best estimate of the solar $\delta^{15}\text{N}$ value is $-407 \pm 7\text{‰}$ (Marty et al. 2011). These results suggest that essentially all nitrogen-bearing solid compounds contained in asteroidal materials or naturally including the Earth-forming building blocks are enriched in ^{15}N .

Nitrogen Isotopes on the Earth

Although the extent of nitrogen isotope variations among terrestrial samples is much smaller than among the extraterrestrial ones, likely reflecting the isotope homogenization produced by intensive heating and mixing of the accreted materials, important variations in the isotopic ratio are still observed; for instance, between nitrogen in the mantle layers (-3‰ for the MORB source mantle, or $+3\text{‰}$ for the OIB source mantle; reference in Marty and Dauphas 2003) and the atmosphere ($\equiv 0\text{‰}$), or between nitrogen trapped in contemporary sediments ($+7\text{‰}$) and Archean sediments (-7 to $+40\text{‰}$; compiled by Thomazo et al. 2009).

The possibilities proposed so far to explain these isotopic variations can be divided into two groups with the keywords somewhat similar to the extraterrestrial case: “heterogeneity” or “fractionation.” The hypotheses belonging to the first group (e.g., Jia and Kerrich 2004) refer to the contrasting isotopic compositions among chondrites as analogues for the Earth-forming building blocks. The typical end-member compositions

assumed in such models are the bulk compositions of the Enstatite chondrites ($-22 \pm 11\%$; average and standard deviation in the distributions among bulk $\delta^{15}\text{N}$ values) and the carbonaceous (CI/CM) chondrites ($+35 \pm 11\%$). The other group attempts to explain the variations by isotopic fractionation on the Earth, particularly at its surface, where nitrogen actively circulates between the atmosphere and the biosphere. It is commonly accepted that the average of 5‰ enrichment of ^{15}N in the contemporary marine biosphere, relative to the atmosphere, is caused by a biological cycle of N. This cycle involves *fixation* ($\text{N}_2 \rightarrow \text{NH}_4^+$), *nitrification* ($\text{NH}_4^+ \rightarrow \text{NO}_3^-$), and *denitrification* ($\text{NO}_3^- \rightarrow \text{N}_2$), where the biological N ($\text{NH}_4^+ + \text{NO}_3^-$) is enriched in ^{15}N due to the preferential consumption of ^{14}N in the last process (Sigman et al. 2008). Several workers (e.g., Shen et al. 2006) argue that part of the $\delta^{15}\text{N}$ variations (7–40‰) observed among the sedimentary rocks of different ages can be explained by a similar cycle but with different fluxes composing the cycle, possibly reflecting the different environmental settings. For instance, we may expect higher mean $\delta^{15}\text{N}$ values for the biosphere when the flux of *denitrification* in the cycle was larger. Such a situation may happen when the abundance of free oxygen was lower in the atmosphere and in the ocean, where the nitrate ion, an electron acceptor substituting for the role of free-oxygen, was more important for life than at present. Alternatively, the negative $\delta^{15}\text{N}$ values can be produced by the isotope fractionation involved in chemosynthesis: organic production uses chemical energy instead of sunlight (deep-sea hydrothermal vents) (Pinti and Hashizume 2001). Other models (Marty and Dauphas 2003; Goldblatt et al. 2009) the isotopic differences among the mantle layers and the atmosphere relate to the biological isotope fractionation. These authors suggest that nitrogen delivery takes place as NH_4^+ ions substituting for K^+ ions in the subducting crustal rocks. Ammonium ions are predominantly produced through life. By this mechanism, the peculiar isotopic signatures of present and past living organisms may be propagated to the mantle.

Nitrogen Isotope Fractionation

The prominent isotope variations that occur for nitrogen may not be absolutely indifferent to the geochemical nature of nitrogen. The most abundant phase of nitrogen in the proto-solar nebula or at the surface of the Earth, in a wide range of pressure-temperature conditions, is the exceedingly stable gas phase, the triple-bonded nitrogen bimolecule N_2 . The bimolecular nitrogen is so inert that little is trapped among the solid materials. The dominant fraction of nitrogen observed in the planetary solid materials or N-rich terrestrial rocks is trapped as chemically active nitrogen-bearing compounds. The formation processes of these compounds probably bear the key to understanding the origin of the nitrogen isotope fractionation. To yield any nitrogen-bearing solid compounds from N_2 , it is indispensable to first go through a particularly energy-consuming elementary process to cut the triple bonds. The elementary processes proposed so far involve excitation sources or catalysts peculiar to the specific environments, such as cosmic rays (for ion-molecule reactions), ultraviolet light (for photodissociation), or enzymes available in limited kinds of microorganisms (for nitrogen fixation in the ocean). The observed nitrogen isotope variations are directly associated with these processes (e.g., Clayton 2002), and/or, as a consequence of the limitations caused by the existence of this energy barrier: nitrogen-bearing solid compounds are effectively produced only through a few pathways involving the bond-cutting elementary processes. The isotopic signatures specific to each pathway (e.g., Rodgers and Charnley 2008; Sigman et al. 2008) could be therefore easily preserved.

Future Directions

The overall situation of current nitrogen isotope studies is not specific to nitrogen. Remarkable isotope variations observed among the planetary and terrestrial samples, and some contrasting and unresolved explanations presented, are often shared by other elements. This is the case of volatile elements in extraterrestrial samples (e.g., H, C, and O; Clayton 2002) and of

biologically important and/or redox-sensitive elements in terrestrial rocks (e.g., C, S, and Fe; Thomazo et al. 2009). The similarity and dissimilarity isotope signatures for elements from various samples are the most promising clues to the entire stable isotope puzzle.

Nitrogen Sulfide (NS)

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Synonyms

NS

Definition

The term nitrogen sulfide is used both for solid N_4S_4 (also called nitrogen tetrasulfide), which is unstable under laboratory conditions, and by astronomers for the diatomic, gas phase molecule NS. The latter is widespread in interstellar ► [molecular clouds](#), with an enhanced abundance in ► [“hot cores”](#), the regions where massive stars are forming. Gaseous NS has been observed in the ► [Milky Way](#) and in external galaxies as well as in ► [Comets](#).

History

Interstellar NS was first detected by radio astronomers in 1975 by Gottlieb et al. (1975) and Kuiper et al. (1975).

Definition

The noble gases are a group of chemical elements with a very low chemical reactivity. In most natural conditions, they cannot form chemical compounds and their abundances and isotopic ratios are only affected by physical processes such as phase changes, kinetic effects, and nuclear reactions including radioactivity. Due to their inertness, they are used as cosmochemical and geochemical tracers when investigating the origin and the processing of their host phases or of other volatile elements.

Overview

The noble gases – helium (symbol: He), neon (Ne), argon (Ar), krypton (Kr), xenon (Xe), and radon (Rn) – have all their electronic shells saturated and therefore cannot readily make

compounds. Radon isotopes are all instable and this element is generally not used as a geochemical tracer. Although they are abundant in stars (helium is the second most abundant element in the universe), they are highly depleted in metals and silicates, and therefore in inner planets and meteorites, due to their impossibility to make chemical bonds with other elements. For instance, terrestrial noble gases, when normalized to a reference element like silicon, are depleted by factors of 10^{-6} – 10^{-10} relative to the solar photosphere. They are particularly useful as cosmochemical and geochemical tracers because of their inertness and their low natural background. They record physical processes such as fractionation during phase changes or irradiation, or nuclear production of some of their isotopes, by spallation or neutron/proton activation in space or at the Earth's surface, or by decay of naturally occurring radioactive isotopes. The well-known K-Ar geochronological method makes use of the decay of potassium-40, a rare isotope of the otherwise relatively abundant element potassium, to ^{40}Ar (half life $T_{1/2} = 1.25$ Ga), an isotope of argon that was in very low abundance compared to the other isotopes of argon, ^{36}Ar and ^{38}Ar , when the Earth formed. Noble gases are also excellent tracers of the formation and evolution of the atmospheres of the terrestrial planets. For instance, air contains 0.934% of Ar, formed almost exclusively of ^{40}Ar produced by the decay of radioactive potassium in the solid Earth, which testifies of the degassing of the mantle into the atmosphere through time. Other noble gas isotopic systems including extant and extinct radioactivities, such as ^{129}I - ^{129}Xe ($T_{1/2} = 16$ Ma), ^{244}Pu - $^{131-136}\text{Xe}$ ($T_{1/2} = 82$ Ma), and ^{238}U - $^{131-136}\text{Xe}$ ($T_{1/2} = 4.45$ Ga), have allowed considerable refinement in modeling the origin and evolution of the atmospheres of Earth and ► [Mars](#). Noble gases in the Sun and in meteorites present elemental and isotopic variations that can be used to set constraints on the origin of terrestrial volatiles. Noble gas elemental and/or isotopic fractionation during phase change and kinetic processing permits investigation of the responsible processes, such as oil–water–gas interactions in the crust, or atmospheric escape early in Earth's history.

Noise

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

Noise is an unwanted and random perturbation on a signal of interest. Any measurement is affected by noise, which can be fundamental (e.g., shot noise), instrumental (e.g., vibrations), or due to a perturbing medium (e.g., atmospheric turbulence). When noise sources are independent, their signals add in a quadratic way. The signal-to-noise ratio (usually noted S/N) is the ratio of the magnitude of the useful signal to the noise amplitude: it is a convenient way to assess the relative importance of a disturbing effect. The result of an experiment established with a $S/N < 5$ is generally considered as not reliable.

Definition

Amino acids are multifunctional organic compounds that contain at least one amino and one carboxyl group attached to a central carbon atom,

whose side chains may vary in length and branching as well as in content of other functional groups or aromatic rings. Amino acids may form numerous molecular structures, where the relative position of the amino and carboxyl function allows their general classification as 2-, 3-, 4-, etc. (also referred to as α , β , γ , etc.) amino acids. Most amino acids have at least one asymmetric carbon and are chiral. Amino acids are classified as nonprotein when they are not part of the 22 such molecules that are translated into proteins by the standard [genetic code](#). They are found in nature, both in biology and extraterrestrial chemistry.

Overview

A large and diverse number of amino acid molecular species not found in proteins have been discovered in the biosphere and in extraterrestrial environments. The finding of amino acids synthesized via abiotic processes has particular astrobiological significance, as it shows that compounds similar or identical to the biomolecules indispensable to extant life's structure and function can be formed abiotically and outside of the Earth's biochemistry.

Amino acids are abundant compounds in the biosphere as the monomeric constituents of proteins where they are assembled according to genetic instructions that originate in a distinct DNA triplet code for each. Evolution has limited their number to 20 species and their type to L-[enantiomers](#) of α -amino acids with the general formula shown in Scheme 1, where R is H for the simplest compound (2-carbon [glycine](#)) or an alkyl chain of variable composition. In the only exception of proline (Scheme 2f), the amino group is secondary and the alkyl chain is cyclic. Two additional amino acids of rare distribution, *selenocysteine* and *pyrrolysine*, were recently discovered in several bacteria and are also genetically encoded. The finding would suggest that the standard 20-amino acid alphabet could be expanded during certain evolutionary contingencies and more amino acids may still remain to be found in translated protein chains.

Nonprotein Amino Acids, Scheme 1 The general structural formula of the α -amino acids found in proteins

Some rare amino acids of distinctive composition are also observed in the hydrolyzates of specialized functional proteins but are formed by enzymatic modification of amino acids already transcribed in the polypeptide chains. They have limited distribution and are necessary to the specific function of the protein. The often quoted examples are the unusual *desmosine* and *isodesmosine* molecules that occur in the fibrous chains of the elastin. These amino acids have a central pyridine molecule with four amino acid branches of various chain lengths (C2–C4), which can crosslink in a radial setting to other polypeptide chains and help the protein to contract and expand.

Nonprotein Amino Acids

Amino acids can occur as molecular species of numerous structural arrangements, where the varying amino to carboxyl relative position, extent of alkyl chain elongation, substitution along the chain or the amino group, and additional functional groups and/or chiral carbons in the R-chain allow several homologous series of a large number of compounds (Scheme 2). It is in the free form or combined with other compounds, but not as protein or with L-configuration only, that diverse types of amino acids are found in nature as part of biochemistry as well as extraterrestrial chemistry. As biological and abiotic processes usually dictate, they have distinctive metabolic functions in the first case and stochastic diversity in the latter.

Nonprotein amino acids in biology are frequently variations of protein amino acids, some

Nonprotein Amino Acids, Scheme 2 The possible structural formulas of nonprotein amino acids (b–h)

are metabolites or intermediates in metabolism and others can be part of biological structures. Examples are β -alanine [$CH_2(NH_2)CH_2COOH$], a building block of pantothenic acid (vitamin B_5); γ -amino butyric acid [$CH_2(NH_2)CH_2CH_2COOH$], a neurotransmitter in the brain of mammals that is produced by decarboxylation of glutamic acid; and D- α -alanine, a constituent of the complex cell walls of some bacteria. Fungi, bacteria, and plants also contain a large variety of other amino acids. Many of these are toxic to foreign organisms, by inhibiting or disrupting existing proteins; these toxic effects may fulfill an ecological role in the plants that produce them, for example, as deterrents toward predators or by inhibiting the growth of competing plant species (Bell 2003).

A subgroup of α -amino acids, the 2-amino-2-methyl acids (Scheme 2b), have been studied in particular detail because they are constituents of antibiotics. These compounds are found in a number of fungi *genera* as short helical peptides exhibiting antibiotic activity against bacteria as

well as fungi and are called peptaibols because they contain α -aminoisobutyric acid (AIB) or peptabiotics to summarize their properties. About 850 peptaibols have been described, whose antibiotic function is based on their ability to insert in the lipid layers of bacterial/fungal membranes and form voltage-dependent ion channels through which cytoplasmic material can leak, eventually leading to cell death (Toniolo and Brückner 2009).

Nonprotein Amino Acids in Cosmochemistry

Amino acids can form in extraterrestrial environments, and the largest variety of their possible molecular species has been found in a group of carbon-containing meteorites, the carbonaceous chondrites (CC). Like most meteorites, CC are fragments of asteroids, the odd-sized and shaped planetesimals that orbit the sun in great number between Mars and Jupiter. They represent the remnants of a planet that never formed due to Jupiter's large interfering gravity and, by the

frequent collisions of their crowded trajectories, frequently send fragments into the Earth's orbit as meteors and meteorites. Not having suffered the extreme physicochemical conditions of planet formation or having reached a large enough size to separate matter on the basis of density, CC parent bodies are aggregate rocks that may contain a pristine record of early solar system processes. In fact, some of these planetesimals have been recently discovered in the main asteroid belt that behave like comets, by emitting comae of dust fueled by sublimation (Hsieh and Jewitt 2006).

As a result of their provenance and carbon content, CC meteoritic fragments offer unique samples of extraterrestrial organic chemistry, as it came to be in the solar system at the time the Earth was formed and before life began on Earth (see also meteorite (Orgueil), carbonaceous chondrites (organic chemistry of), ► carbonation). CC meteorites are often collected in large enough quantities for detailed laboratory analyses and have been extensively studied since the first recorded fall of the Alais meteorite in 1806. The modern era of these studies started in 1969 with the fall of the Murchison meteorite because, at the time, the laboratories of the National Aeronautics and Space Administration were preparing for the return of lunar samples and were able to analyze this meteorite shortly after its fall. The first surprising revelation of these analyses was the discovery of racemic amino acids and, since proteins are made up of only L-amino acids, this finding excluded terrestrial contamination as their source. The finding also established the first analytical understanding of prebiotic chemistry and suggested a possible exobiology. Over 100 amino acids have been observed in the Murchison meteorite and similar CC by gas chromatographic analyses with mass spectroscopy detection (GC/MS), and at least 80 have been identified on the basis of reference standards. They represent nearly all possible isomeric and homologous species with the basic formulas listed in Scheme 2 and up to their limit of solubility in water (approximately eight-carbon chain length). Eight protein amino acids were also found in Murchison: ► glycine, ► alanine, ► valine, ► leucine, ► isoleucine, ► proline, and aspartic and glutamic acids. Four more (► serine,

► threonine, tyrosine, and phenylalanine) were recently found in another type of CC (see below). Besides the diversity of molecular species, Murchison amino acids are also characterized by declining abundances with increased molecular weight, a compositional trait suggesting that the growth of their carbon chains might have involved the stepwise addition of smaller carbon moieties.

In another family of CC, the Renazzo-type or CR, amino acids have shown a different distribution, with overall larger abundance of the compounds but with their number restricted to fewer and smaller amino acid species, such as glycine, alanine, and AIB. As mentioned above, some protein amino acids not found in the Murchison-type meteorites were detected in CRs bringing to 12 the total number of meteoritic amino acids having biological counterparts in terrestrial proteins. This selective composition and the fact that amino acids and ammonia are the most abundant soluble components of these meteorites have a particular prebiotic significance because it suggests that their abundance might have led to association into oligopeptides under prebiotic conditions.

Another notable subgroup of amino acids present in Murchison and similar type of meteorites might also have held an important advantage in prebiotic times. These are the α -substituted α -amino acids shown in Scheme 2b that, when chiral as in ► isovaline, were found to be non-racemic and to display varying enantiomeric excesses (ee) that, if not as large, have the same sign, L-, of the amino acids in terrestrial proteins (Cronin and Pizzarello 1997). The finding was validated by isotopic analyses (see below) and represents the only case of molecular asymmetry measured so far outside the biosphere. Because meteoritic amino acids have abundantly showered the early Earth and amino acids can be asymmetric catalysts (Pizzarello and Weber 2004), it has been proposed that these compounds might have contributed to terrestrial molecular evolution and the induction of homochirality.

The origin of amino acids e.e. in meteorites is not known and may be related to several physicochemical influences encountered by the compounds during their syntheses in cosmic

environments. One often proposed hypothesis is that of their partial photolysis by ultraviolet (UV) circular polarized light (CPL). This radiation possesses true ► [chirality](#) and interacts differently with the enantiomers of a chiral molecule. If the energy of the radiation is high, as in the case of UV, the two enantiomers will be destroyed at different rates and extent with resulting e.e. for the molecule.

Because the biosphere is pervasive on the Earth and meteorites fall protected only by a thin ► [fusion crust](#) that easily fissures with impact, the indigeneity of meteoritic amino acids having counterpart in terrestrial proteins has been questioned in some cases, especially in regard to the abundance of their L-enantiomers. However, their extraterrestrial origin has been established unequivocally by measurement of their isotopic composition. As explained in isotopic fractionation, the zero-point energy differences between isotopes' bonds may lead to mass-dependent isotopic fractionation in molecules during reactions that, in turn, becomes a possible indicator of the synthetic reactions undergone by a molecule. Since this fractionation takes the form $\exp^{\Delta E/T}$, it is expected to be highest for ► [deuterium](#) (D) and to decrease with temperature. This expectation is confirmed by the large D/H (► [deuterium/hydrogen ratio](#)) fractionation observed spectroscopically for the molecules in the dense clouds of the interstellar medium (ISM), where T may be as low as 5–10 K. By the analyses of their D, ^{13}C , and ^{14}N composition, all meteoritic amino acids have shown an enrichment of the heavy isotopes of these elements that excludes their terrestrial formation. The origin of meteoritic amino acids was also elucidated, albeit in general terms, by these analyses and, in particular, their D/H content. As these compounds were found to be enriched in deuterium, with D/H values that sometimes near those determined for ISM molecules, the finding was interpreted to indicate their general lineage to

cold cosmic regimes, such as those of the ISM. It is interesting to note that the higher values between Murchison and CR amino acids were found to belong to AIB and non-racemic isovaline.

Certainly, the synthetic routes that lead to meteoritic amino acids' formation were not direct and might have involved several precursor molecules as well as periods of water availability in the asteroidal parent body. Also, the variety of amino acid molecular species determined in Murchison-type meteorites preclude a single explanation for the synthetic routes responsible for their formation. One pathway to α -amino acids might have been important and that is the cyanohydrin addition of HCN to aldehydes and ketones in the presence of water and ammonia as shown in Scheme 3.

The occurrence of this reaction seems confirmed by the presence in meteorites of hydroxy acids, compounds that differ from amino acids in having a hydroxyl (OH) instead of an amino group and would have formed concomitant to amino acid during a parent body aqueous phase. This synthetic route also relates both groups of compounds to aldehydes and ketones, a class of extraterrestrial compounds that have been detected in a variety of cosmic environments, including the ISM.

Basic Methodology

Amino acids contain both acidic and basic functional groups, i.e., amphoteric compounds that can ionize at different pHs to be present as cations, zwitterions, or anions. In water and at physiological pH, they are present as zwitterions and have different charges at the amino and carboxyl groups with a net charge of zero.

Based on these molecular properties, amino acids are readily soluble in water and

Nonprotein Amino Acids, Scheme 3 The cyanohydrin reaction

methodologies for their extraction, separation from other molecular species, and characterization start with water solutions. When isolated, and concentrated or dried as needed, amino acids are analyzed by a variety of liquid as well as gas chromatographic methodologies. In either method, columns coated with chiral phases can be used to establish amino acid's enantiomeric D/L ratios.

Applications

AIB, isovaline, and some of their higher homologues have been used in small peptides with pharmacological function (e.g., as antibiotics). Some plant amino acids are also mentioned that are toxic to animals and insects and can be used in agriculture as pesticides.

Future Directions

Future studies of nonprotein amino acids will expand on the current applications in the drug, chemical, and biosynthetic industries. In the research field of astrobiology, they will focus on establishing these amino acids' origin and their prebiotic traits, such as chiral asymmetry.

Nordic Network of Astrobiology

William M. Irvine
Department of Astronomy, University of
Massachusetts Amherst, Amherst, MA, USA

Definition

The Nordic Network of Astrobiology is a network of some 20 research institutions in the Nordic and Baltic countries. Among its aims are promoting research in astrobiology, fostering cooperation in

research and graduate training, organizing courses and holding scientific conferences in astrobiology, promoting public awareness of the field, informing national and international science funding and space research agencies about research in astrobiology, and collaborating with other astrobiology institutions worldwide. The Nordic Network is an Affiliated Partner of the NASA Astrobiology Institute (NAI).

Definition

The North Pole Dome, located at the center of the East Pilbara Granite-Greenstone Terrane, Western

Australia (North Shaw, AMG 746500E 7663100N), is an Archean terrane containing little-deformed, dominantly mafic volcanic rocks of the ► [Warrawoona Group](#), which form the Panorama greenstone belt. These successions, covering a ca. 25×35 km area, are arranged in a broad dome around a central nucleus occupied by a 3.5-Ga-old magmatic intrusion named the “North Pole Monzogranite.” The southwestern part of the North Pole Dome contains what the scientific community considers as the oldest ► [stromatolites](#) so far recognized on Earth, at the famous “Trendall locality” of the Strelley Pool Formation. Several Archean rock sequences were altered by Archean episodes of hydrothermal fluid circulation and ► [weathering](#); they have been used to test hyperspectral remote sensing instrumentation for detecting analog hydrothermal systems on ► [Mars](#).

Overview

Archean rock units at the North Pole Dome are arranged as follows (from base to top):

1. The North Pole Monzogranite (monzogranite is a biotite-rich granite) with an age between $3,459 \pm 18$ Ma (Thorpe et al. 1992), and $3,454 \pm 17$ Ma (Asanuma et al. 2018).
2. The $3,490 \pm 15$ -Ma-old North Star metabasalts that surrounds the North Pole Monzogranite at the core of the dome.
3. Five stromatolitic chert-barite horizons interbedded with pillowed basalts, collectively referred to as the $3,481 \pm 2$ -Ma-old Dresser Formation (previously called the Towers Formation).
4. Mafic rocks of the $3,469 \pm 3$ -Ma-old Mount Ada Basalt and a thin felsic volcanoclastic chert of the ca. 3,467-Ma-old Duffer Formation.
5. A 4-km-thick section of the Apex Basalt capped by up to 1.3 km of 3,459–3,452-Ma-old felsic volcanic and volcanoclastic rocks of the Panorama Formation.
6. The 3,430-Ma-old Strelley Pool Formation (formerly called Strelley Pool Chert), a 10–30 m thick succession of characteristically

white and gray layered cherts containing the distinctive conical stromatolites of the Trendall locality.

7. A thick (up to 9.4 km) succession of interbedded high-Mg and tholeiitic basalts and various cherts of the 3,395–3,346-Ma-old Euro Basalt Formation.

The rocks have been metamorphosed from prehnite-pumpellyite to lower greenschist facies, and a contact-metamorphic aureole is developed around the North Pole Monzogranite (Van Kranendonk et al. 2001).

Although the North Pole Dome is a rather insignificant small granitoid among larger batholiths outcropping in the Eastern ► **Pilbara Craton**, this place has a particular interest for astrobiology and the search of ancient life. Indeed, the oldest

► **stromatolites** and MISS (microbially induced sedimentary structures) have been found within the 3,490-Ma-old Dresser Formation and the 3,430-Ma-old Strelley Pool Formation (e.g., Hofmann et al. 1999; Allwood et al. 2007; Noffke et al. 2013; Duda et al. 2016), at the so-called Trendall locality (named after its discoverer, in 1984, Australian geologist Alec Trendall).

The stratiform chert-barite units of the Dresser Formation are fed by a set of chert-barite dikes that were emplaced within, and immediately above, listric normal growth faults that were active during deposition of the cherts (Nijman et al. 1998). These thousands of dikes have been interpreted as remains of white and black smoker chimneys. The carbon (Ueno et al. 2004, 2006) and nitrogen (Pinti et al. 2001, 2009) isotopic composition of kerogen and carbon filaments

found in those cherts have been variably interpreted as representing the products of metabolic activity of methanogens and chemoautolithotrophs surviving around mid-Archean thermal ponds. Finally, airborne hyperspectral remote sensing surveys have been done on the hydrothermal altered rocks of the North Pole Dome, especially in relation with stromatolitic sites, to set instrumentation for detecting similar features on the surface of Mars (Brown et al. 2005) (Figs. 1 and 2).

Definition

Since July 1, 2009, the Netherlands Space Office (NSO) is acting as the space agency for the Netherlands. NSO concentrates Dutch space policy in one organization. NSO reports directly to a steering committee of involved ministries (Economic Affairs; Education, Culture and Science; Science and Education; Transport, Public Works and Water Management). It develops and carries out the space program for the Netherlands.

The Space Office represents the Netherlands in an international space context (to other space agencies, including ESA) and acts as the single point of contact for space policy and implementation in the space area. One of its roles is to strengthen communication about space activities to stakeholders, students and educators, and the general public. NSO counts around 25 permanent people.

Another organization, namely, the SRON (Netherlands Institute for Space Research) is the Dutch expertise institute for space research. The institute focuses on astrophysical research, earth science, and exoplanet research. More than 200 permanent and temporary employees are spread between the two laboratories based in Utrecht and in Groningen.

Nuclear Reaction

Alain Coc
 IJCLab (Laboratoire Irène Joliot-Curie),
 Université Paris-Saclay, Orsay, France

Keywords

Energy · Nuclei · Nucleosynthesis

Definition

Nuclear reactions are processes that lead to the modification of the composition, structure, or internal energy of atomic nuclei.

History

The first laboratory experiment to demonstrate nuclear transmutation via a nuclear reaction was conducted by Rutherford in 1919, bombarding ^{14}N with α -particles, producing ^{17}O , and liberating a proton through the reaction:

Overview

Nuclear reactions play an important role in astrophysics as they are the source of energy of most stars and, through nucleosynthesis, are at the origin of the chemical elements. In general, a nuclear reaction results from the collision between two atomic nuclei producing one or more nuclei, possibly in excited states, together with the release or absorption of energy. One of its most important characteristics is its cross-section, which measures its probability to occur. The cross-section has the dimension of a surface and is given in units of barn (b) equivalent to 10^{-24} cm^2 . Some important reactions that involve electrons and neutrinos, like $p + p \rightarrow ^2\text{H} + e^+ + \nu_e$ in the Sun, are mediated by the weak interaction and are considerably slower than those involving the nuclear or even the electromagnetic interaction. Because of their higher cosmic abundances, nuclear reactions involving ^1H (i.e., protons), ^4He (i.e., α -particles) nuclei, or neutrons are of special interest in astrophysics. In particular, the triple-alpha reaction $3 \alpha \rightarrow ^{12}\text{C}$ is at the origin of Carbon in the Universe, thanks to the presence of a nuclear excited level in ^{12}C with favorable properties.

In astrophysics nuclear reactions take place in two distinct environments: a dense medium in thermodynamical equilibrium (typically a stellar interior) or a dilute medium crisscrossed by high-energy nuclei (e.g., interstellar medium). The latter is the site of ► [spallation reactions](#) whose cross-sections as a function of energy are the relevant quantities. The former is the site of thermonuclear reactions, characterized by their rates. Thermonuclear reaction rates are just the cross-sections, averaged over the Maxwell–Boltzmann distribution of the interacting nuclei, and are a function of temperature.

Spallation reactions, because of the energy involved, have high cross sections and hence can be obtained from laboratory measurements. For reactions taking place in stellar interior, thermal energy is usually low when compared with the Coulomb repulsive potential between nuclei.

Quantum tunneling is hence required for the fusion, leading to very low cross-sections. Laboratory measurements of these cross-sections are a challenge that can only be met for long-lived, light nuclei (i.e., low electric charge). For many reactions, in particular those involved in the r-process with extremely short-lived nuclei, experimental limitations require the extensive use of nuclear theory to estimate cross-sections.

Nuclear Stability

Alain Coc
IJCLab (Laboratoire Irène Joliot-Curie),
Université Paris-Saclay, Orsay, France

Definition

Nuclear stability means that the nucleus of an element is stable and thus it does not decay spontaneously emitting any kind of ► [radioactivity](#). Among the ≈ 9000 nuclei expected to exist, and the ≈ 3000 presently known, only 195 are stable against spontaneous decay, because of energy conservation. In the chart of nuclides, a two-dimensional graph in which one axis represents the number of neutrons and the other represents the number of protons in an atomic nucleus, the

stable nuclei are gathered in the valley of Nuclear Stability. This valley follows at first the line corresponding to nuclei with an equal number of protons and neutrons, and then bends toward the neutron-rich side at higher masses, due to Coulomb repulsion. Those nuclei with the highest ► [binding energy](#) per nucleon are the most stable with respect to destructive nuclear reactions. Note that a few radioactive atoms have lifetimes longer than the age of the Universe (e.g., ^{209}Bi), while others become stable when ionized (e.g., ^7Be).

Nucleation of Dust Grains

Joseph Andrew Nuth III
Solar System Exploration Division, NASA's
Goddard Space Flight Center, Greenbelt, MD,
USA

Keywords

Circumstellar outflows · Condensation · Dust formation · Graphite · Silicates · Interstellar Dust

Definition

Nucleation refers to the dynamic change observed in a system initially consisting of a chemically uniform phase that occurs upon cooling (or heating) to produce a new chemical phase. Such changes occur when a gas, such as water vapor in air, forms liquid droplets upon cooling or an amorphous solid or viscous liquid, such as a glass, forms crystals due to thermal annealing. The water vapor “nucleates” from the gas leaving the air behind. Similarly, the newly formed

crystals may have a different chemical composition than the glass from which they formed.

Overview

Dust grains form in various environments: in circumstellar outflows, after energetic events in protostellar nebulae (such as collisions or lightning), and possibly after the passage of shocks in the ► [interstellar medium](#). Dust surfaces can catalyze a wide range of organic reactions, and the dust itself can control the thermal environment found in many dense astrophysical objects. For these reasons, it is important to understand the properties of freshly condensed dust grains as well as how such properties evolve in response to their environment.

Basic Methodology

The nucleation of dust grains in circumstellar outflows has been addressed both theoretically and via laboratory techniques. Both methods have severe limitations, yet both have produced some useful results. Most studies of grain nucleation focus on the processes that occur in circumstellar winds, though nucleation can occur in other locations (e.g., in nebulae around ► [protostars](#) as well as in many different terrestrial processes). However, the situation in circumstellar outflows is a much better-defined problem: a hot, dust-free gas expands at a measured rate away from a stellar photosphere and at some time afterward forms dust grains that continue to grow until virtually all of the condensable elements have been removed from the gas. Condensed grains might also undergo thermal processing to convert amorphous dust into crystalline material in some outflows. The dust grains in a particular outflow are the ultimate products of nucleation, growth, and annealing. However, this entry will focus exclusively on the nucleation of grains, that is, the transition from a dust-free gas to a two-phase system consisting of gas and the nuclei of liquid/solid material that has the potential to grow into observable dust grains.

For carbon-rich stars, nucleation can in principle be reduced to a problem in chemical kinetics, where a carbon atom or $\text{C}=\text{C}-\text{H}$ radical adds to a growing carbon chain that itself began as a $\text{C}=\text{C}-\text{H}$ radical. Many of the chemical reaction rates are taken from the rich literature on chemical combustion. The chemical pathway to grains in such models leads from ► [radicals](#) to polyaromatic molecules and finally to aggregate grains of cross-linked polyaromatic (or poorly graphitized) carbon. Nucleation in such cases refers only to the formation of the initial distribution of large, polycyclic aromatic hydrocarbon molecules. Models of this type were first suggested by Frenklach and Feigelson (1989) for circumstellar shells, while a variation of this model was suggested by Clayton et al. (1999) to account for the formation of carbonaceous grains in the shells of supernovae. The major problem with this approach is that there is no evidence that the chemical pathway proposed is the one actually taken in a carbon-rich astrophysical system. A minor problem is that not all of the chemical kinetic rate constants used in the model have been measured in the laboratory. The most popular way around these problems is to ignore the nucleation process altogether.

Tsuji (1964) first calculated the temperature-dependent composition of stellar atmospheres based on the assumption that the atoms, molecules, and solids in such systems would remain in chemical equilibrium. This model completely eliminates all of the uncertainties involved in the kinetic calculations discussed above and is based on a chemical thermodynamic database established by the chemical industry and the academic community and supported by government agencies. This model's greatest strength is also its greatest weakness since it always assumes the formation of the most stable chemical compounds and cannot account for observed species such as amorphous silicate or poorly graphitized carbon. Chemical species left out of the calculation simply "do not form." In addition, no information on the number density of particles or on their size distribution can be obtained from such models. In the most formal sense, when the model predicts that

half of the available aluminum is in corundum, this means that there is one and only one very large grain of corundum at equilibrium in the stellar atmosphere.

There is a compromise that combines elements of both thermodynamic and kinetic modeling that was formulated to calculate the rate of water droplet formation in a supersaturated atmosphere. Donn et al. (1968) first suggested the potential application of classical nucleation theory (Becker and Döring 1935) to the formation of grains in stellar outflows. Nucleation theory allows calculation of the rate of grain formation per unit volume and also allows calculation of the final grain-size distribution generated by a given trajectory in composition, density, and temperature (Gail and Sedlmayr 1999) if one is willing to make a few additional assumptions about the fraction of impinging atoms that stick to growing grains or the fraction that evaporate from a hot surface. The problem with nucleation theory is that the rate of grain formation strongly depends upon an ill-determined parameter known as surface energy.

Surface energy is the “force” that tends to make droplets round or that pulls two adjacent drops together to form a single drop with greatly reduced surface/volume ratio. An atom or molecule on a surface has a higher energy than one in the interior of a grain because it cannot be fully bonded with surrounding species. Nature tends to minimize the total energy of a system, so high surface/volume systems are unstable with respect to low surface/volume systems (e.g., small droplets will always grow into larger droplets by aggregation; it takes energy to break large droplets into smaller ones). It is difficult to measure the surface energies of important astrophysical compounds such as graphite, amorphous carbon, or amorphous silicates, and one can easily find differences in measurements reported in the literature ranging from factors of 10 up to factors of 20,000 for specific compounds. Unfortunately, the calculated rate of nucleation depends upon the exponential of the cube of the surface energy; therefore, a factor of 20 difference in the value of the surface energy used in a calculation leads to a factor of about 485 million difference in the

calculated nucleation rate. This difference is large, even by astrophysical standards.

In theory, it should be possible to carry out experimental studies of the nucleation of refractory vapors such as SiO in a hydrogen atmosphere from which one could derive the surface energy of the condensing grains. Indeed, such experiments have been carried out (Nuth and Donn 1982, 1983). However, there are problems. Astrophysical systems present an intriguing set of challenges for laboratory chemists. Most such chemistry occurs in atmospheric regions that would be considered an excellent vacuum by terrestrial laboratory standards and at temperatures that would quickly vaporize normal laboratory equipment. Timescales for changes in state variables such as temperature, pressure, and composition range from milliseconds to minutes for rapid events, like collisions or electric discharges. Outflows around asymptotic giant branch (AGB) stars have timescales ranging from seconds to weeks depending on the distance of the region of interest from the star, and on the way significant changes in the state variables are defined. “Steady-state” protostellar systems evolve on timescales ranging from centuries to millions of years, while the atmospheres in normal stars may only change significantly on several billion-year timescales. Needless to say, most laboratory experiments carried out to understand astrophysical processes are not carried out under conditions that perfectly match the natural suite of state variables or the timescales appropriate for changes under natural conditions. Experimenters must, of necessity make appropriate use of simple analog experiments that seek to place limits on the behavior of natural systems, often extrapolating the knowledge gained from such experiments to much lower pressure and/or significantly higher temperature environments.

Experimental studies of the nucleation of refractory materials, such as silicates, are rare. Most astrophysical studies of grain formation focus simply on the spectral properties of the grains produced in the experiment rather than on the mechanism of grain formation. Additional studies follow the spectral evolution of newly formed dust in response to environmental

parameters such as hydration or thermal annealing. Experimental studies of SiO nucleation have been published (Nuth et al. 2000), but the results of these studies are currently being revised in light of new vapor pressure data for SiO (Ferguson and Nuth 2008). The published studies did provide a measurement of the surface energy for SiO nuclei, and the reanalysis should provide a more accurate estimate of this quantity for use in model calculations based on nucleation theory.

Nucleation studies of single component refractory grains (SiO, Fe, Ag, Li, Na, K, Mg, and Ca) can be found in the literature; however, studies of the nucleation process in multielement systems cannot. Studies of the properties of grains formed from complex vapors are available, and these have presented some surprises: the smallest grains produced in the experiments are thermodynamically unstable but seem to form at metastable eutectic compositions (Rietmeijer et al. 1999). Many additional three condensate systems have been explored, and all seem to show such behavior, as do naturally occurring systems such as volcanic ash, or man-made particulates such as smoke from coal-fueled power generators (Rietmeijer et al. 2000). From an astrophysical perspective, the most important result of these studies is that mixed vapors of iron, magnesium, and SiO will nucleate amorphous magnesium silicates and iron silicates, but not mixed magnesium silicate-iron silicate grains. Mixed grains only form after coagulation and annealing of the primary condensates. The formation of separate populations of pure iron silicate and magnesium silicate grains could help explain observations of pure magnesium silicate minerals in some high mass outflow rate circumstellar winds.

Nucleation theory combines a quasi-steady-state thermodynamic cluster distribution with a simple kinetic model for both cluster growth and the growth of stable dust grains, the molecular “sticking” efficiency is frequently neglected in nucleation models. Most models simply assume that condensing atoms or molecules stick with near-unit efficiency whenever they strike a growing cluster or dust grain. In circumstellar outflows, the assumption of unit sticking efficiency makes

little difference for the pre-condensation cluster size distribution (Paquette and Nuth 2011); however, the value of the grain growth efficiency factor can make a huge difference (Nuth et al. 2020). An experimental study of the growth of zinc grains under microgravity conditions, where buoyancy-driven convection is not a factor, demonstrated that only three in $\sim 10^5$ zinc atoms that collided with a growing grain actually stuck (Michael et al. 2003). A study of the nucleation of iron grains in a sounding rocket experiment (Kimura et al. 2017) similarly determined that only a few atoms in every 10^5 that struck a growing iron grain were incorporated into the final dust particle. The difference between unit grain growth sticking efficiency and efficiencies closer to 10^{-5} makes a difference in the final grain size of many orders of magnitude and spread grain growth from a relatively concentrated area to a much larger fraction of the outflow.

Key Research Findings

Theory and modeling in this area have not produced reliable results, though experimental studies still leave much to be desired. There is a lot of work to do both experimentally and in the application of experimental data to astrophysical systems. Reliable surface energy data may soon be available for SiO condensation, while metastable eutectic condensation may limit the composition of the initial condensates in circumstellar outflows. Such compositions should be predictable based both on experimental studies and on available phase diagrams for multicomponent solids. The efficiency of grain growth from the vapor is a key parameter that requires additional study since this factor can have a large effect on the grain population ejected into the interstellar medium.

Applications

Understanding the nucleation process is essential for modeling the dust found in the outflows of dying stars as well as in evaluation of the potential

for surface-mediated processes to catalyze the formation of organic materials in ► [protoplanetary nebulae](#).

Future Directions

More experimental work is needed to understand the specific compositions of the grains that condense from vapors to confirm or refute the hypothesis that such condensates are NOT the thermodynamically predicted mineral species, but rather are metastable condensates that form at metastable eutectic compositions. The thermodynamically stable mineral species evolve from these materials following growth, aggregation, and thermal annealing that promotes diffusion, equilibration, and crystallization.

Adenine · Cytosine · Guanine · Purine base · Pyrimidine base · Thymine · Uracil

Definition

A nucleic acid base (or nucleobase) is a nitrogen heterocyclic compound, which serves as the informational monomer of ribonucleic acids (RNA) and deoxyribonucleic acids (DNA), the biopolymers responsible for the storage and transmission of genetic information. Structurally, nucleic acid bases are substituted purines and pyrimidines

(► [purine bases](#) and ► [pyrimidine bases](#)). The primary nucleic acid bases are adenine, cytosine, guanine, thymine, and uracil. Minor/modified nucleic acid bases are also found in RNA and DNA. Since nucleic acid bases are components of RNA, DNA, and coenzymes, they are broadly distributed in nature.

Overview

A nucleic acid base is a nitrogen heterocyclic compound found in nucleic acids – the most common nucleic acids being ribonucleic acids (RNA) and deoxyribonucleic acids (DNA). In RNA and DNA, nucleic acid bases take the form of substituted purines and pyrimidines and comprise one of the three characteristic components of nucleotides (the other two components being a five-carbon sugar and a phosphate group). In DNA, genetic information is encoded in the linear sequence of nucleotides. A single DNA strand may have millions of nucleotides.

Nucleic acid bases are weakly basic compounds. They are stabilized by resonance among atoms in the ring, which gives most of the bonds partial double bond character. Nucleic acid bases derived from pyrimidines are planar molecules. Nucleic acid bases derived from purines are nearly planar molecules with a slight ring pucker. Since they are aromatic in character, nucleic acid bases are characterized by strong UV absorption (~260 nm). Nucleic acid bases may exist in different tautomeric forms depending on the pH. At neutral pH, they are generally unionized, hydrophobic, and therefore relatively insoluble.

The primary nucleic acid bases are adenine, cytosine, guanine, thymine, and uracil. Two properties of nucleic acid bases important in maintaining the overall structure and stability of DNA (and RNA) are hydrogen bonding and base stacking interactions. A ► [base pair](#) usually involves hydrogen bonding between a purine and a pyrimidine (see Watson-Crick pairing). In DNA, guanine base pairs with cytosine, while adenine base pairs with thymine. In RNA, uracil replaces thymine and pairs with adenine. Other types of base-pairing configurations exist, such as

Hoogsteen base pairing. Usually purine-purine and pyrimidine-pyrimidine base pairs (also referred to as base-pair mismatches) are both energetically unfavorable. However, the wobble base pair of inosine-adenine is one example of a purine-purine base pair. When nucleic acid bases are aligned so that the faces of the aromatic rings are parallel to each other, they form non-covalent attractive π -stacking interactions. The sum of all stacking interactions within the nucleic acid creates a large stabilizing effect, which helps maintain the structure of the nucleic acid.

Different starting materials, catalysts, and reaction conditions have been used to synthesize nucleic acid bases under plausibly prebiotic conditions demonstrating that their synthesis was likely robust (see ► [purine bases](#) and pyrimidine bases for some examples). Two well-studied compounds for the synthesis of nucleic acid bases are hydrogen cyanide (HCN) and formamide (NH_2COH). At high concentrations ($\sim >0.01$ M), HCN forms heterogeneous polymers in water, which may have been an important source of both nucleic acid bases and amino acids. For example, a plethora of biological and nonstandard nucleic acid bases have been detected in frozen mixtures of HCN and NH_3 after acid and base ► [hydrolysis](#). When HCN concentration in water is low (without eutectic freezing), hydrolysis to formamide is favored over polymerization. While this pathway is unlikely to produce significant amounts of formamide, other sources of formamide may exist. Additionally, formamide can be concentrated by evaporation (such as in the drying lagoon model). One-pot syntheses of nucleic acid bases have been achieved using formamide in the presence of various catalysts such as alumina, calcium carbonate, iron sulfur and iron-copper sulfur minerals, kaolin, ► [montmorillonite](#), olivine, silica, titanium dioxide, and zeolites. Again, both standard and nonstandard nucleic acid bases are produced, which presents interesting scenarios for the origin of the first ► [genetic code](#).

Minor/modified nucleobases exist in DNA and RNA, and their existence has been suggested to be relics from the ► [RNA world](#) (hypothesis). The incorporation of modified nucleobases into

nucleic acids can alter properties such as charge, conformation, base pairing, base stacking, hydration, and/or coordination with metal ions. In the laboratory, enzymatic incorporation of alternative base pairs into duplex DNA and RNA has been demonstrated. Consequently, an expanded genetic alphabet could lead to greater functional diversity as well as the possibility of greater catalytic ability. It is plausible that the first genetic material contained alternative nucleobases, since they are also produced in the synthesis of the canonical nucleobases and have similar properties (e.g., stability, Watson-Crick base pairing, etc.).

Nucleic acid bases (in the free form and in the gas phase) are unlikely to form and survive in interstellar and circumstellar environments since they eventually decompose in the presence of intense UV radiation. However, nucleic acid bases may be able to survive if located in a dense ► [interstellar cloud](#), although no positive detection has been made yet. Additionally, nucleic acid bases may survive if offered protection from irradiation. For example, they may exist in some precursor form (perhaps bound in the macromolecular component of a meteorite) or protected by ices or grains.

Conversely, UV irradiation may also have played an important role in forming nucleic acid bases. UV photolysis of pyrimidine in pure water over the temperature range 20–120 K yielded uracil. It is worth mentioning that these products may have formed during warm-up since the organic residue is brought to room temperature and removed from the experimental apparatus for ex situ analysis. However, similar “warm-up” events may occur naturally on Earth, for example, by impact events. Also, these results indicate that pyrimidine mixed with water ice is more stable against UV photodegradation than isolated pyrimidine. The nucleic acid base adenine has been reportedly produced from ► [Titan](#) atmosphere analogues irradiated by soft X-rays. In this experiment, a gas mixture simulating the Titan atmosphere (95% N₂, 5% CH₄) was deposited on a cooled substrate (maintained at 14 K) and irradiated by soft X-rays. Adenine was detected in the acid-hydrolyzed organic residue (after warm-up)

and characterized by ¹H NMR spectroscopy and gas chromatography/mass spectrometry. Again warming is necessary to remove the organic residue for ex situ analysis. On the surface of Titan, warming may be similarly achieved during a comet impact or volcanism event.

Cryogenic conditions are not necessary for the formation of nucleic acid bases; therefore, nucleic acid base synthesis on the primitive Earth is also likely. Solar UV light would be one of the most abundant and readily accessible sources of energy on the primitive earth. For example, uracil was produced in the laboratory by UV irradiation of a mixture of urea and β-alanine in the presence of clay minerals. Uracil was also produced by the photochemical decarboxylation of orotic acid (a pyrimidine formed by hydrolysis of HCN oligomers) under plausible prebiotic conditions.

Photostability of nucleic acid bases is an often overlooked property that may have been important for ► [prebiotic chemistry](#), especially when considering the possible prebiotic environment on the early Earth. Nucleic acid bases are UV chromophores in RNA and DNA and the absorption of UV photons can result in photodamage of the nucleic acid. On the early Earth, the absence of an ozone layer allowed for increased exposure of short wavelength UV light. Thus, the genomic information encoded in DNA (i.e., the nucleic acid bases) would have been under constant photochemical attack. This vulnerability is compensated by means of enzymatic repair. It is conceivable that on the early Earth, such enzymatic repair mechanisms may not have existed yet. In addition, enzymatic repair is energetically costly. Fortunately, nucleic acid bases are intrinsically photostable. This is due to the existence of ultrafast pathways that remove the electronic energy of the nucleic acid base to the surrounding (solution) environment in the form of heat as demonstrated by femtosecond laser spectroscopy and theoretical modeling of the excited state dynamics. UV photostability may have been an important factor for the evolutionary selection of the biological nucleic acid bases in addition to their capability to base pair and base stack. Alternatively, avoiding photodamage may ultimately

constrain the environments in which nucleic acid bases can survive.

Finally, the tantalizing suggestion of meteorites and comets delivering nucleic acid bases should be mentioned. The pyrimidine uracil and the purines adenine, guanine, hypoxanthine, and xanthine have been detected in carbonaceous chondrites. More recently, purines not typically found in biochemistry have also been detected in meteorites, including 2,6- and 6,8-diaminopurine as well as purine itself. While still controversial, extraterrestrial signatures in the compound-specific carbon isotopic measurements of uracil and xanthine previously detected in the Murchison meteorite have been reported.

Definition

Nucleic acids are long, unbranched polymers of nucleotides. Each nucleotide monomer consists of a nitrogenous base, a pentose sugar, plus a phosphate group. Nucleotides polymerize by chemically linking a phosphate group at the 5' position of one nucleotide to the hydroxyl group at the 3' position of the next nucleotide. The linkage creates a phosphodiester bond, releasing a water molecule. In its two principal forms, ribonucleic acid (RNA) and deoxyribonucleic acid (DNA), nucleic acids store, transcribe, and translate genetic information into the diverse array of proteins needed for execution of almost every cellular process.

Overview

The large, complex molecules of life are carbon-based, and fall into four broad categories: carbohydrates, lipids, proteins, and nucleic acids. Carbohydrates, the simplest of which are sugars, provide energy and structure. Lipids include various steroids, isoprenoid compounds, fatty acids, and amphipathic phospholipids that make up cellular membranes. Proteins, which are composed of amino acids, are involved in almost every cellular process: catalysis, recognition, transport, regulation, and structure. The fourth major category is nucleic acids. Nucleic acids store, transcribe, and translate genetic information into a diverse and preprogrammed array of proteins.

The fundamental units (or monomers) that compose ► [DNA](#) and ► [RNA](#) are called ► [nucleotides](#) (Saenger 1984). A nucleotide contains a planar, nitrogen-containing heterocycle called a base. A base is either a single-ring pyrimidine or a double-ring purine. In addition to a base, each nucleotide contains a phosphate group and a five-carbon sugar, either ribose or deoxyribose (see Fig. 1a). Phosphate groups can be attached to either the 5' or the 3' positions of the sugar. Nucleotides can contain multiple phosphates as in adenosine triphosphate (ATP), which contains three phosphate groups in series, at the 5' position. When all phosphate groups are removed from a nucleotide, it is called a ► [nucleoside](#). ► [Nucleotides](#) are polymerized to form nucleic acids (DNA and RNA), but nucleic acid monomers and dimers also play critical roles in many cellular processes. ATP is the primary energy storage and transfer molecule of all living systems. Nicotinamide adenine dinucleotide (NAD^+ , Fig. 1b) contains adenosine 5' diphosphate, as does Flavin adenine dinucleotide (FAD^+). NAD^+ and FAD^+ are oxidizing agents (electron acceptors) in important biochemical processes (Voet and Voet 2003). cAMP (3', 5'-cyclic adenylic acid) is a signaling compound. It transmits signals that originate with hormones, such as glucagon and adrenaline, within cells. cAMP regulates protein kinase and Ca^{2+} levels (Voet and Voet 2003).

Nucleotides are polymerized in cells to form long linear chains (Fig. 2) used to encode genetic

Nucleic Acids, Fig. 1

(a) The nucleotide adenosine triphosphate (ATP). Removal of one phosphate by the addition of water produces adenosine diphosphate (ADP). Removal of the second phosphate produces adenosine monophosphate (AMP). (b) The dinucleotide nicotinamide adenine dinucleotide (NAD⁺)

information in all living systems. Two types of five-carbon sugar are contained in nucleic acid polymers: 2'-deoxyribose is found in DNA, while ribose is found in RNA. In DNA's 2' deoxyribose, the 2' carbon is bonded to two hydrogen atoms. In RNA's ribose, one of those hydrogen atoms is replaced by a hydroxyl group. This difference in the sugars of DNA and RNA has a profound impact on the lability of the phosphodiester backbone. RNA hydrolyzes much more quickly than DNA, especially in the presence of magnesium ions. It is commonly said that RNA is less stable than DNA, although the 2' hydroxyl group of RNA reduces the *kinetic barrier* to backbone hydrolysis. The difference in

backbone hydrolysis of RNA and DNA is kinetic rather than thermodynamic.

One of the nitrogen-containing bases of DNA differs slightly from its RNA counterpart. The purines guanine (G) and adenine (A), and the pyrimidine cytosine (C), are common to DNA and RNA. The distinguishing base is thymine (T) in DNA and uracil (U) in RNA. A methyl group of T is replaced by a hydrogen atom in U. In both DNA and RNA, the bases are attached to the sugars at the 1' position through a B-N glycoside linkage. Polymerization of nucleotides, which creates the "phosphodiester backbone," is achieved through phosphate ester bonds, in which a phosphate group joins the 5' hydroxyl group of

Nucleic Acids, Fig. 3 Watson-Crick base pairs, in which two hydrogen bonds (*dashes*) link T with A while three hydrogen bonds link C with G. The bases are colored by type: adenine (*red*), thymine (*blue*), cytosine (*green*), and guanine (*purple*). Note that in DNA, A pairs only with T and C pairs only with G

neutral; (iii) a nucleotide unit is longer, with more bonds and greater flexibility than an amino acid; (iv) the side chains of nucleic acids (the bases) are planar and uncharged, while the side chains of proteins vary in size, shape, flexibility, polarity, and charge; and (v) nucleic acids readily assemble by side chain-side chain interactions (base pairs), while proteins primarily assemble by backbone-backbone interactions (α -helices and β -sheets).

In cells, DNA codes for messenger RNA (mRNA) that in turn codes for protein. This direction of the flow of genetic information is known as the central dogma of biology (Crick 1970), which is almost universally employed by extant life.

There is support for abiotic synthesis (Oró and Kimball 1962) and extraterrestrial delivery (Schmitt-Kopplin et al. 2010) of nucleic acid precursors to Earth. Purine and ► **pyrimidine bases** have been identified, with supporting carbon isotope dating, in carbonaceous chondrites such as the Murchison meteorite that fell in Australia in 1969 (for a review see Schmitt-Kopplin et al. 2010).

Nucleic Acids, Fig. 4 The B-form DNA double helix shown in reduced form for simplicity. The phosphate groups are not shown. The bases are colored by type, as in Fig. 3

Deoxyribonucleic Acid (DNA)

Specific pairing of purine and pyrimidine bases in a double helix (Fig. 4) was first proposed by James D. Watson and Francis Crick in 1953. This “B-form” helical structure contains nucleic acid bases paired by hydrogen bonds. In the B-form, base pairs are centered on the helical axis, with the base pair normals coincident with the axis. DNA bases stack like pennies in a roll.

The sugar-phosphate backbones fall on the outside to form an antiparallel, right-handed helix. Base pair stacking, rather than hydrogen bonding, makes the greatest contribution to duplex stability (Devoe and Tinoco 1962). The B-form helix, with a repeat of around ~ 10.3 base pairs, contains a wide major groove and a narrow minor groove.

Elucidation of the base pairing scheme was aided by Erwin Chargaff’s observation that the ratios of

A to T and C to G are very close to 1:1 in a variety of species (Zamenhof et al. 1952). In addition, Watson and Crick's model incorporated results of DNA fiber diffraction experiments carried out by Rosalind Franklin (Franklin and Gosling 1953).

The importance of Watson and Crick's model, along with work by Linus Pauling and others on protein structure, is that it greatly facilitated a unification of chemical and biological sciences, leading to the creation of the fields of biochemistry and molecular biology. The structure of DNA allowed the incorporation of the basic concepts of chemistry – hydrogen bonding, van der Waals interactions (stacking), bond angles, and torsions – into the practice and understanding of biological sciences. As Watson and Crick noted, "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material."

The ease of manipulation of DNA has fostered its extensive use in the study of essentially all cellular components. Identification of specific DNA sequences (restriction sites) cleaved by restriction enzymes (Roberts 1976) led to the development of recombinant DNA technology, in which targeted DNA sequences are essentially cut, copied, and pasted into other DNA sequences. It was later found that DNA polymerases and oligodeoxyribonucleotide primers (short pieces of DNA) can be used to amplify essentially any target sequence from genomic DNA using what is called the ► [polymerase chain reaction](#) (PCR) (Mullis and Faloona 1987).

Ribonucleic Acid (RNA)

According to the ► [RNA world](#) hypothesis (Rich 1962), articulated in detail by Gilbert (1986), a single type of molecule served as both genetic information carrier and catalyst in primitive living systems. In this model for the origin of life, genetic RNA was replicated by catalytic RNA. A single polymer fulfilled essentially all of life's requirements, avoiding the chicken and egg dilemma presented by extant biochemistry – which came first, catalytic proteins or genetic nucleic acids? The RNA world hypothesis provides a reasonable answer: RNA came first, with both catalytic and genetic functions. A smooth and continuous evolutionary pathway from

catalytic RNA to protein enzymes was paved with mixed RNA/protein assemblies (Poole et al. 1998). Support for the RNA World hypothesis is found in observations that RNA performs catalytic functions in extant biology (Kruger et al. 1982; Guerrier-Takada et al. 1983).

RNA, like DNA, can form right-handed anti-parallel duplexes with stacked base pairs. RNA duplexes give A-form helices, in which the base pairs are displaced from the helical axis, and are rolled, so that their normals are not parallel to the helical axis. RNA's A-form helix is thicker and more compressed along the helical axis than DNA's B-form helix.

Unlike DNA, RNA forms complex three-dimensional structures dictated by combinations of secondary and tertiary interactions between bases, and by cation-mediated interactions between phosphate groups. The result is distinct folds, such as the L-shaped structure of transfer RNAs (tRNAs) (Fig. 5), or more complex structures such as ribosomal RNAs (rRNAs).

RNA polymerase transcribes DNA into mRNA, which carries sequence information to the ribosome (Kornberg 2007). The ► [ribosome](#) translates the mRNA into protein with the assistance of tRNAs specific to each amino acid.

Ribosomes are around 200 Å in diameter and are comprised of 65% rRNA and 35% ribosomal proteins. They can be either cytoplasmic or membrane bound, depending on the protein actively in synthesis. Ribosomes and their subunits are classified by their Svedberg unit (rate of sedimentation in centrifugation), which ranges from 35S to 100S. Prokaryotes, mitochondria, and ► [chloroplasts](#) have 70S ribosomes (comprised of a small 30S subunit and a large 50S subunit), and eukaryotes have 80S ribosomes (with a small 40S and large 60S subunit). The small 30S and 40S subunits have their own subunits consisting entirely of rRNA: the 16S or 18S subunit, respectively. It is believed that mitochondria and chloroplasts are relict bacterial endosymbionts.

Until 1977, the generally accepted evolutionary relationship among known species was represented by two kingdoms: prokaryotes (bacteria) and eukaryotes. Carl Woese and George Fox used sequences of 16S rRNA to support reclassification of a portion of the prokaryotes into a third kingdom,

Nucleic Acids,

Fig. 5 The L-shaped structure of transfer RNA (tRNA). The bases are colored by type as in Figs. 3 and 4. Here U is blue. Close inspection of the right panel reveals that the base pairs are shifted away from the helical axis, as expected for an A-form helix

later dubbed Archaea (Woese and Fox 1977). Woese and Fox found 16S rRNA genes to be among the most highly conserved in sequence over the phylogenetic tree. Their approach has been widely accepted and is a standard for phylogenetic classification, so that more than 10,000 16S rRNAs have been sequenced to date.

Other RNAs include miRNA and siRNA, responsible for defensive RNA degradation, and snoRNAs that guide ribonucleoproteins to target sites on rRNA for modification.

X-ray crystallography has been used to determine the three-dimensional structure of the atoms in molecules such as the ribosome. The 2010 Nobel Prize in chemistry was awarded to Ada Yonath, Tom Steitz, and Venki Ramakrishnan for ribosomal structure determination. Superimposition of the atomic coordinates of crystallized 50S subunits from *Haloarcula marismortui* and *Thermus thermophilus*, species representing disparate regions of the evolutionary tree, along with other information, suggests that the core of the ribosome is an ancient molecular fossil that predates coded protein (Hsiao et al. 2009). In part, these findings have led to the search for the ancestral peptidyl transferase center (or “ancestral PTC”) of the ribosome, the minimal rRNA necessary for folding and general condensation to produce proto-proteins.

Basic Methodology

- **Oligonucleotide** synthesis. Many DNA oligonucleotides are readily obtained by automated chemical synthesis (often on solid support, with synthesis occurring in the 3′–5′ direction) at lengths of up to 100 nucleotides. Chemical synthesis of RNA is more difficult but the technology has improved substantially over the last decade. Most labs outsource their synthesis to highly efficient commercial enterprises.
- **DNA sequencing** is the determination of the sequence of the nucleotides A, C, G, and T in a nucleic acid. DNA sequencing technology is highly mature. A modern, high-throughput method uses fluorescent dye labeled chain terminator dideoxynucleotide triphosphates in a single sequencing reaction.
- **Restriction**. DNA can be cut at defined positions in a sequence by commercially available restriction enzymes. Commonly utilized type II enzymes cleave DNA within a specific palindromic recognition sequence (compared to type I enzymes that cleave DNA far from the recognition sequence at random) producing DNA with blunt or dangling ends of known sequence.

- Ligation. DNA fragments can be linked by a ligase such as T4, which catalyzes the formation of a phosphodiester bond between a 3' terminal hydroxyl and 5' terminal phosphate in duplex DNA. Ligases are commercially available.
 - Polymerase Chain Reaction. PCR is the amplification of DNA sequences from short oligonucleotides or target regions of plasmid or genomic DNA. Target sequences are amplified with primers containing a short sequence complementary to the target sequence and extraneous specific sequences coding for restriction sites and/or promoters. One primer anneals to the sense strand and the other to the antisense strand of the DNA. A DNA polymerase performs the amplification work by creating new strands of DNA, with loose dNTPs added to the reaction. Amplification with primers containing specific restriction sites allows for subsequent ligation into a bacterial plasmid also containing those restriction sites.
 - ► [Electrophoresis](#). A basic technique used to separate nucleic acids by length, shape, or protein association in a fluid covered matrix (such as agar or polyacrylamide) by an external electric field.
 - RNA Transcription. DNA with a promoter region (such as T7) can be transcribed to produce single-stranded RNA in vitro with RNA polymerase.
 - Crystallography. The coordinates of atoms in molecules such as DNA, RNA, or protein complexes of either can be resolved in three dimensions using X-ray diffraction crystallography, the technique of growing crystals in solution by slowly lowering the solubility of component molecules, mounting the crystals on a loop, and irradiating them with a beam of monochromatic X-rays through a 180° rotation.

Definition

In chemistry and physics, a nucleon is the collective name for the two subatomic particles, the neutron and the proton. Nucleons are constituents of the atomic nucleus. They are composed of still smaller subatomic particles, the quarks.

Definition

Nucleosides are ribosides and deoxyribosides of purine and pyrimidine nucleic acid bases (nucleobases) formed via beta-glycoside linkage to ring nitrogen atoms. The canonical ribonucleosides in RNA are adenosine, cytidine, guanosine, and uridine. In DNA, deoxythymidine replaces uridine and deoxyribose replaces the ribose moieties of adenosine, cytidine, and guanosine. Chemically modified nucleosides are also found in RNA and DNA, where they play functional roles in regulation, translation, and protection from viral infection, as well as in tRNA (transfer RNA) and rRNA (ribosomal RNA) where they play structural roles. These species include methylated adenines and cytosines as well as hydroxymethylated, aminoacylated, and glucosylated species.

Overview

Plausible, robust prebiotic syntheses of the nucleosides in DNA and RNA are among the most pressing unsolved problems in origin of life research (Orgel 2004; Switzer 2009). The prebiotic synthesis of ► [adenine](#) was accomplished by Oró in 1960 from ammonium cyanide, and variations of the synthesis yielded guanine, xanthine, hypoxanthine, and diaminopurine (Orgel 2004). Similar mixtures of purines have also been made by Saladino and coworkers from formamide (Orgel 2004). Syntheses of uracil and ► [cytosine](#) from cyanoacetaldehyde, the hydration product of cyanoacetylene, and urea or guanidine are efficient and also produce small amounts of isocytosine and diaminopyrimidine (Robertson and Miller 1995a). Formaldehyde reacts readily with uracil to make 5-hydroxymethyluracil, which can be readily reduced to thymine with formate (Robertson and Miller 1995b).

The instability and low yields of ribose from the ► [formose reaction](#) have been considered serious barriers, but the addition of lead, borate, or silicate ions to the reaction increases the yield (Zubay 1998; Ricardo et al. 2004; Lambert et al.

2010). Deoxyribose is somewhat more stable and reactive than ribose (Larralde et al. 1995; Dworkin et al. 2003), but fewer studies have been done on this sugar.

Adenosine, guanosine, xanthosine, and inosine have been made in significant yields by heating dry ribose, Mg^{2+} , and sodium metaphosphate with adenine, guanine, xanthine, and ► [hypoxanthine](#), respectively (Orgel 2004; Switzer 2009). Unfortunately, analogous experiments with ► [pyrimidine bases](#) have been unsuccessful except with 2-pyrimidone, which readily forms zebularine (Bean et al. 2007). To get around this difficulty, attempts have been made to start with ribose and build up the pyrimidine ring de novo by Sanchez and Orgel (Orgel 2004; Switzer 2009). Alternatively, Sutherland and colleagues have reacted glycolaldehyde with cyanamide and constructed both the ribose and pyrimidine moieties together by sequential addition of glyceraldehyde, cyanoacetylene, urea, and pyrophosphate followed by UV irradiation (Powner et al. 2009). This procedure produces cytidine and uridine 2'-3'-cyclic phosphates. Progress is being made, but a great deal more research needs to be done to develop robust syntheses of nucleosides or ► [nucleotides](#).

Because of these difficulties, analogues in which either the sugars or the bases have been altered have been synthesized for origin of life research (Eschenmoser 1999; Dworkin et al. 2003), DNA sequencing, cancer and AIDS chemotherapy, and other applications (Sismour and Benner 2005). These compounds include C-glycosides like the naturally occurring pseudouridine.

[Activated nucleotide](#)

Definition

In chemical evolution and related fields, a nucleoside phosphorimidazolidine is defined as “a nucleoside 5'-monophosphorimidazolidine,” where imidazole is a leaving group bound to the phosphate of a nucleoside 5'-monophosphate via an N-P bond. Nucleoside phosphorimidazolidines are a kind of ► [activated nucleotide](#). The leaving group supplies energy to form ► [oligonucleotides](#) from the nucleoside phosphorimidazolidine. Prebiotic experiments have showed that nucleoside 5'-phosphorimidazolidine monomers form ► [RNA](#) oligomers up to 50 nucleotide units in length in the presence of metal catalysts, clay mineral catalysts, or a polynucleotide template.

Overview

The accumulation of RNA molecules should have been an essential step for the emergence of life-like systems on the primitive earth. In modern organisms, polymerization of RNA monomers merely proceeds under the specific conditions, of which thermodynamics and kinetics allow the biochemical polymerization in organisms. Nucleoside 5'-triphosphate monomers are only used to

synthesize RNA polymers in organisms. The cleavage of phosphoester bonding within triphosphate moiety supplies energy for the formation of phosphodiester bonding of RNA oligomers. Furthermore, the polymerization of the nucleoside 5'-triphosphate is accelerated by an RNA polymerase and directed by a DNA template in organisms giving the 3'-5' isomers in a selective way. In the absence of an RNA polymerase or the absence of a DNA template, the polymerization of 5'-triphosphate does not proceed. In addition, it is known that RNA polymers are formed from nucleoside 5'-diphosphate in the presence of polynucleotide phosphorylase without a DNA template. The formation of DNA molecules also proceeds by similar mechanism. In these reactions using 5'-triphosphate or 5'-diphosphate, the phosphoester bonding within the 5'-triphosphate or 5'-diphosphate moieties provides sufficient energy for the formation of phosphodiester bonding of RNA polymers. This indicates that high-energy nucleotide monomers should have been essential for the formation of RNA polymers under the primitive earth conditions.

Thus, the pathways to form RNA polymers without an enzyme and a template molecule have been investigated under the simulated primitive earth conditions. Continuous investigations by Orgel and coworkers have identified nucleoside 5'-phosphorimidazolidine, a candidate primitive activated nucleotide monomer for the first time (Lohrmann and Orgel 1973; Orgel and Lohrmann 1974). The formation of nucleoside 5'-phosphorimidazolidine proceeds under the potential primitive earth conditions (Lohrmann 1977). The nucleoside 5'-phosphorimidazolidine and related compounds have been examined whether oligonucleotides could be formed from these materials under the primitive earth conditions. Successful studies including RNA oligomer formation in the presence of metal catalysts (Sawai 1976), clay mineral catalyst (Ferris and Ertem 1992; Ferris et al. 1996), and a polynucleotide template (Inoue and Orgel 1983) showed RNA oligomers up to 50 nucleotide units in length form under primitive earth conditions. The variations using different bases instead of imidazole also facilitate the formation of oligonucleotides (Huang and Ferris 2006).

Nucleosynthesis, Explosive

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Synonyms

[Explosive nucleosynthesis](#)

Definition

Explosive nucleosynthesis refers to nucleosynthetic processes occurring in stellar explosions (supernovae, novae, X- and γ -ray bursts, etc.). Because of the short timescale, important weak interactions (modifying the neutron/proton ratio

N/Z) have no time to occur. Several chemical elements, like iron (Fe), gold (Au) or uranium (U) are produced in such explosions. In particular, explosive Si-burning (fusion) in core collapse and thermonuclear supernovae produces mostly ^{56}Ni ($N = Z = 28$), which decays to stable ^{56}Fe ; the characteristic γ -ray lines of the decay were detected in ► [supernova](#) SN1987A and SN2014J, confirming the theoretical predictions. The so-called r-nuclides (heavier than iron and neutron-rich) are also produced by explosive nucleosynthesis, through the rapid capture of neutrons in the innermost regions of core collapse supernovae or neutron star collisions.

Nucleosynthesis, Neutrino

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

Neutrino nucleosynthesis refers to the non-thermonuclear mode of nucleosynthesis occurring during the explosion of a massive star. A fraction of the 10^{58} neutrinos released by the supernova has energies comparable to the binding energies of the heavy nuclei (several MeV/nucleon) which are found in the various supernova layers. Neutrinos knock out one particle from abundant nuclei creating lighter and less abundant ones, e.g., ^{11}B from ^{12}C or ^{19}F from ^{20}Ne .

Nuclear reactions · Stars · Stellar evolution · Supernovae

Definition

Stellar nucleosynthesis is the process involving ► [nuclear reactions](#) through which fresh atomic nuclei are synthesized from pre-existing nuclei or nucleons. The first stage of nucleosynthesis occurred in the hot, early Universe, with the production of H, He, and traces of Li-7 (*primordial nucleosynthesis*). In the present-day Universe nucleosynthesis occurs through: (1) thermonuclear reactions in stellar interiors and explosions (building nuclei up to the Fe-peak), (2) neutron captures in stellar interiors and explosions (building nuclei above the Fe-peak), and (3) ► [spallation reactions](#) in the interstellar medium, whereby light nuclei (Li, Be, and B) are produced by fragmentation of heavier ones (C, N, and O).

History

The theory of nucleosynthesis emerged around the middle of the twentieth century as a result of rapid progress in our understanding of three different fields: (1) the chemical composition of the Sun and the solar system, (2) the physical conditions prevailing in the interiors of ► [stars](#) during their various evolutionary stages, and (3) the systematic properties of nuclei and nuclear reactions.

Overview

The solar or cosmic abundances of the various nuclear species (Fig. 1, upper panel) constitute an important macroscopic property of (baryonic) matter. This property is rather closely related to a microscopic one, namely the “binding energy per nucleon” (BEN, lower panel in Fig. 1). The latter quantity represents the energy per nucleon required to break a nucleus into its constituent particles and is a measure of the ► [nuclear stability](#).

The key features of the BEN curve are obviously reflected in the cosmic abundance curve, albeit at a local level only: more stable nuclei are more abundant than their neighbors (e.g., nuclei built from alpha particles – ${}^4\text{He}$ – such as ${}^{12}\text{C}$, ${}^{16}\text{O}$, or ${}^{40}\text{Ca}$; or the Fe-peak nuclei), while the fragile Li, Be, and B isotopes are extremely under abundant. However, at a global level, the light H and He are overwhelmingly more abundant than the more strongly bound C, N, and O, which in turn

are more abundant than the even more stable Fe-peak nuclei. The (local) correlation between cosmic abundances and nuclear stability suggests that nuclear reactions have shaped the abundances of elements in the Universe. The fact that the correlation is only local and does not hold at a global level implies that nuclear processes have affected only a small fraction of the baryonic matter in the Universe (less than a few per cent).

Searching for the sites of nuclear reactions, which shaped the cosmic abundances, has been the main theme of nuclear astrophysics in the past half century. It is now well established that:

- The light isotopes of H and He, along with 10–30% of the fragile ${}^7\text{Li}$, have been produced in the hot early Universe by thermonuclear reactions between neutrons and protons.
- All the elements between C and the Fe-peak have been produced by thermonuclear reactions inside stars, either during their quiescent evolutionary stages or during the violent

Nucleosynthesis, Stellar,

Fig. 1 Solar abundances on a logarithmic scale of the stable nuclei (*top*), and corresponding binding energies of these nuclei (*bottom*) vs. mass number

explosions (supernovae) that mark the deaths of some stars.

- Elements heavier than those of the Fe-peak have been produced by neutron captures in stars, either in low neutron densities and long timescales (s- elements) or in high neutron densities and short timescales (r- elements); a minor fraction of those heavy elements has been produced by photodisintegration of the heavy isotopes in supernova explosions (p-isotopes).
- Finally, the light and fragile isotopes of Li, Be, and B are not produced in stellar interiors (they are rather destroyed in high temperatures), but by ► [spallation reactions](#), with high energy cosmic ray particles removing nucleons from the abundant C, N, and O nuclei of the interstellar medium.

In the following, we focus on the *stellar nucleosynthesis* of heavy nuclei, which are much more important than the light nuclei for the origin of terrestrial planets and of life. This topic is tightly linked to the properties of stellar interiors. In this review, we follow astronomical practice and refer to nuclear fusion reactions as “burning.” We likewise use nuclear physics notation, writing the reaction $X + b \rightarrow c + D$ as $X(b,c)D$ and using α and γ to denote an alpha particle (${}^4\text{He}$ nucleus) and gamma-ray, respectively. Moreover, we use A and Z to denote atomic weight (number of neutrons plus protons in the nucleus) and atomic number (nuclear electric charge), respectively.

Quiescent Nucleosynthesis

H-Burning in Main Sequence Stars

Most of the stars in the Universe shine by converting H to ${}^4\text{He}$. However, only $\sim 15\%$ of the cosmic abundance of ${}^4\text{He}$ is produced by stars (otherwise, the cosmic background of optical light would exceed by far the observed one): more than 80% of it has been produced in the Big Bang by the *primordial nucleosynthesis*. In stars of mass $< 1.2 M_{\odot}$ and central temperatures below 20 million K, most of the H-burning energy is released by the ► [p-p chains](#). In stars of higher

masses and temperatures, H-burning occurs through the ► [CNO cycle](#), where the C, N, and O isotopes (produced from previous stellar generations) act as catalysts. The sum of the abundances of CNO nuclei remains constant throughout H-burning, but there is an internal rearrangement: ${}^{12}\text{C}$ and ${}^{16}\text{O}$ turn into ${}^{14}\text{N}$ and, to a smaller extent, into ${}^{13}\text{C}$ and ${}^{17}\text{O}$; these are the main nuclei produced by the CNO cycle.

He-Burning in Red Giants

After H exhaustion, the stellar core contracts and releases gravitational energy, which brings the surrounding H-rich layers to temperatures high enough for H-burning reactions. At the same time, the envelope expands and cools and the star turns into a *red giant* (or super giant for the most massive of them, i.e., above $10 M_{\odot}$). The envelope of such a star is convective and brings to the surface products of the previous central H-burning phase. Enhanced abundances of ${}^4\text{He}$ and ${}^{14}\text{N}$, as well as modified isotopic ratios of, e.g., ${}^{13}\text{C}/{}^{12}\text{C}$ or ${}^{17}\text{O}/{}^{16}\text{O}$, are the marks of this “1st dredge-up” phase, which allows one to compare nucleosynthesis theory to observations.

When the H-exhausted core reaches temperatures of 100–200 millions K (with higher temperatures corresponding to higher stellar masses), He fusion begins. The process is known as the triple-alpha reaction and proceeds in two steps (${}^4\text{He} + {}^4\text{He} \rightarrow {}^8\text{Be}$ and ${}^8\text{Be} + {}^4\text{He} \rightarrow {}^{12}\text{C}$) with the second one involving a resonant reaction; the final outcome is the formation of a ${}^{12}\text{C}$ nucleus from three alpha particles.

In the very beginning of He-burning, at temperatures of ~ 100 MK, ${}^{14}\text{N}$ turns into ${}^{18}\text{O}$ and later into ${}^{22}\text{Ne}$, through successive alpha-particle captures. Thus, He-burning constitutes the production mode of ${}^{18}\text{O}$ in the Universe, since some amount of it survives in the He-shell the subsequent reaction ${}^{18}\text{O}(\alpha, \gamma){}^{22}\text{Ne}$. In late He-burning, ${}^{12}\text{C}$ nuclei capture α particles to form ${}^{16}\text{O}$ nuclei; the ${}^{12}\text{C}(\alpha, \gamma){}^{16}\text{O}$ reaction is not resonant, however, so that at central He-exhaustion a considerable amount of ${}^{12}\text{C}$ is left over in the stellar core. ${}^{16}\text{O}$ is usually dominant at that stage, but the exact ${}^{16}\text{O}/{}^{12}\text{C}$ ratio depends on the rate of the ${}^{12}\text{C}(\alpha, \gamma){}^{16}\text{O}$ reaction, which is still uncertain.

Toward the end of core He-burning in massive stars, at temperatures of 250 MK, neutrons are released through $^{22}\text{Ne}(\alpha, n)^{25}\text{Mg}$. As they lack an electric charge, those neutrons are easily captured by all nuclei in the star (in proportion to the corresponding neutron capture cross sections). A part of those nuclei is destroyed in subsequent stages of the evolution of massive stars, but those that survive are ejected by the final supernova explosion. This “weak $\blacktriangleright$ s-process” leads to the production of the light s-nuclei, with mass number A between 60 and 90. Heavier s-nuclei are produced during the AGB phase of shell He-burning in low and intermediate mass stars, where neutrons are released mainly through $^{13}\text{C}(\alpha, n)$.

In AGB stars, material from the He-burning layer is mixed first in the H-layer and finally in the convective stellar envelope (“3d dredge-up” phase). The enrichment of the latter with He-burning products leads to the appearance of “Carbon stars” and “s-stars.” Such late evolutionary stages provide important tests for theories of $\blacktriangleright$ stellar evolution and nucleosynthesis. This is also the case with the most massive stars (with initial masses above $30 M_{\odot}$), which develop strong stellar winds, due to the high radiation pressure on their envelopes. Losing more than $10^{-5} M_{\odot}$ per year, they finally reveal layers that have been affected by nucleosynthesis. The products of core H-burning (^4He and ^{14}N) and then of core He-burning (^{12}C , ^{16}O , and ^{22}Ne) appear thus with enhanced abundances on the stellar surface. Those stars are called *Wolf-Rayet stars*, and their spectroscopy offers another invaluable test of nucleosynthesis theories.

Advanced Nuclear Burning in Massive Stars

Despite their small number (less than 1% of a stellar generation), massive stars constitute the most important agents of galactic chemical evolution. Indeed, most of the elements heavier than helium in the Universe are synthesized in the hot interiors of massive stars and, in particular, during the final *supernova* explosion. Contrary to their lower mass counterparts, which stop evolving after burning He in a shell surrounding an inert

Carbon-Oxygen core, stars with mass $M > 10 M_{\odot}$ burn successively all the available nuclear fuels in their core, until its composition is dominated by nuclei of the iron peak. However, the duration of all stages subsequent to core He-burning is so short that no direct observational tests of the evolutionary status of the core (which is hidden inside a red supergiant envelope) are possible. Only “post-mortem” observations offer a possibility of (indirectly) validating the results of the models (Fig. 2).

Neutrino Losses

One of the most important features of the advanced evolutionary stages of massive stars is the copious production of neutrinos, due to the high temperatures and densities reached in the stellar core after He-exhaustion ($T > 0.8$ GK, density $> 10^5 \text{ g cm}^{-3}$). Neutrino-antineutrino pairs are produced by: (1) *electron-positron annihilation*, the e^{-} 's and e^{+} 's being created by the hot thermal plasma; (2) *photo-neutrino process*, analogous to Compton scattering, with the outgoing photon replaced by a neutrino-antineutrino pair; and (3) *plasma process*, where a *plasmon* (an excitation of the plasma) decays into a neutrino-antineutrino pair.

Neutrinos interact only weakly with matter and escape easily from the stellar core, taking away most of the available thermal energy (produced by nuclear reactions and/or gravitational contraction). In order to compensate for that neutrino “hemorrhage,” the core has to increase its nuclear energy production, by contracting and increasing its temperature. As a result, the evolution of the star is greatly accelerated: the time between C-ignition and the final supernova explosion is less than 0.1% of the corresponding main sequence lifetime.

C, Ne, and O Burning

C-burning in massive stars occurs at temperature $T \sim 0.8$ GK and density $\sim 10^5 \text{ g cm}^{-3}$. The core composition at C-ignition is dominated by the ashes of He-burning, ^{12}C , and ^{16}O (more than 90% of the total) in a proportion that decreases with the stellar mass. The exact proportion of $^{12}\text{C}/^{16}\text{O}$ and the exact initial fraction of ^{12}C (which is crucial for the energetics of C-burning)

Nucleosynthesis, Stellar, Fig. 2 Schematic evolution of the interior composition of a massive star of $25 M_{\odot}$. The central temperatures (T_c) and densities (ρ_c), as well as the approximate durations of the various burning stages,

appear in the bottom. After the final supernova (SN) explosion, a neutron star or a black hole is left behind (SN residue), while the rest is ejected in the interstellar medium, forming the SN remnant

N

depend sensitively on the – still uncertain – value of the $^{12}\text{C}(\alpha, \gamma)^{16}\text{O}$ rate and on the adopted criterion of convection during He-burning. The reason for the latter dependence is that every α particle brought in the convective core while He is almost exhausted (and the rate of the 3α reaction too low to produce new ^{12}C nuclei) converts a ^{12}C nucleus into ^{16}O .

The fusion of two ^{12}C nuclei produces a compound nuclear state of ^{24}Mg , which decays by emitting a proton or an alpha particle. Note that the neutron emission channel, i.e., $^{12}\text{C} + ^{12}\text{C} \rightarrow n + ^{23}\text{Mg}$, corresponds to an endothermic reaction with a small probability (0.1% at $T = 1$ GK) but it is nevertheless important because the decay of ^{23}Mg to ^{23}Na changes the *neutron excess* $\eta = \Sigma(N_i - Z_i)Y_i$, where N_i , Z_i , and $Y_i = X_i/A_i$ are the neutron number, the charge, and the number fraction of nucleus i , respectively. Moreover, neutron captures on heavy nuclei produce heavier than Fe nuclei, thus modifying the s-process composition resulting from the previous

He-burning phase. Also, protons and alphas released by the $^{12}\text{C} + ^{12}\text{C}$ fusion are captured on the ambient nuclei through dozens of (energetically unimportant) reactions; in particular, α captures on ^{20}Ne produce ^{24}Mg . Thus, the main products of C-burning are ^{20}Ne , ^{23}Na , and ^{24}Mg .

After C exhaustion, the composition of the stellar core is dominated by ^{16}O and ^{20}Ne (more than 90% of the total by mass). ^{23}Na and ^{24}Mg also exist at the few per cent level (in mass fraction). Despite its smaller Coulomb barrier, ^{16}O is not the next fuel to burn, since it is exceptionally stable (being a doubly magic nucleus with $Z = N = 8$). The photodisintegration of ^{20}Ne nuclei $^{20}\text{Ne}(\gamma, \alpha)^{16}\text{O}$ becomes energetically feasible at $T \sim 1.5$ GK, i.e., before the fusion temperature of ^{16}O nuclei ($T \sim 2$ GK) is reached. The released α particles are captured on both ^{16}O (to restore ^{20}Ne) and ^{20}Ne (to form ^{24}Mg). The net result of the operation is that this ^{20}Ne “melting” can be described by: $2 ^{20}\text{Ne} \rightarrow ^{16}\text{O} + ^{24}\text{Mg}$.

The photodisintegration of ^{20}Ne is endoergic, but the exoergic α captures on ^{16}O and ^{20}Ne more than compensate for the energy lost. ^{20}Ne burning produces 0.1 MeV/nucleon or 1.1×10^{17} erg/g, i.e., about one-fourth the specific energy released by C-burning. Several other energetically unimportant reactions, induced by p, n, and α particles occur during Ne burning; in particular, ^{23}Na (a product of C-burning) disappears through $^{23}\text{Na}(\text{p}, \alpha)^{20}\text{Ne}$ and $^{23}\text{Na}(\alpha, \text{p})^{26}\text{Mg}$.

After Ne burning, the stellar core consists mainly of ^{16}O , ^{24}Mg , and ^{28}Si . Also, ^{29}Si , ^{30}Si , and ^{32}S are present at the 10^{-2} level (in mass fraction).

The subsequent fusion of two ^{16}O nuclei produces a compound nucleus of ^{32}S which decays through the p, α , and n channels; the corresponding branching ratios and energy released are 58% (7.68 MeV), 36% (9.58 MeV), and 6% (1.45 MeV), respectively. The energy released by oxygen burning is 5×10^{17} erg/g or 0.5 MeV/nucleon. As in the previous stages, dozens of n, p, and α induced reactions occur. However, the increased temperature and density introduce two novel features:

1. Electron captures occur mainly on ^{31}S , ^{30}P , ^{33}S , ^{33}Cl , and ^{37}Ar . These weak interactions modify substantially the neutron excess, up to ~ 0.01 (especially in the lower mass and denser stars); the final neutron-rich composition is clearly non-solar and should be rarely ejected by the star.
2. Photodisintegration reactions become also important and destroy most of the heavier than Fe nuclei that have been built through n captures in the previous burning phases (mostly by s-process during He-burning). However, this happens only in the innermost and hottest regions of the stellar core; outside them, products of previous burning stages survive.

Si-Melting and Nuclear Statistical Equilibrium (NSE)

At O-exhaustion, the composition of the stellar core is dominated by ^{28}Si (30–40% by mass fraction) and, either ^{32}S and ^{38}Ar (in the more massive cores, where low densities do not favor electron

captures) or ^{30}Si and ^{34}S (in the lower mass stars, below $15 M_{\odot}$). ^{28}Si “burns” at temperature $T \sim 3.2$ GK and in a way that is reminiscent of the ^{20}Ne “burning.” The fusion of two ^{28}Si nuclei requires such high temperatures that photodisintegration of all nuclei would result. Instead, part of the ^{28}Si nuclei photodisintegrates, mainly through a sequence of reactions involving α particles: $^{28}\text{Si}(\gamma, \alpha)^{24}\text{Mg}(\gamma, \alpha)^{20}\text{Ne}(\gamma, \alpha)^{16}\text{O}(\gamma, \alpha)^{12}\text{C}(\gamma, 2\alpha)\alpha$.

Other photodisintegration reactions releasing p and n also occur, especially in material with neutron excess substantially different from 0 (due to previous electron captures, i.e., in high density stellar cores). The released α particles and nucleons are further captured by ^{28}Si and heavier nuclei, and equilibrium is established between direct and inverse reactions.

The mean atomic weight of the mixture progressively increases, since free nucleons and α particles are tied to heavier and more strongly bound nuclei; that is why the overall process is better described as *Si-“melting.”* In fact, local equilibrium between a few nuclear species is established already by the end of O-burning, but, as the temperature increases, the various quasi-equilibrium clusters merge. In early Si-melting, there are already two major quasi-equilibrium clusters established: one with nuclei with $A = 24$ –46 and another with Fe peak nuclei. Toward the end of Si-melting, the two clusters merge and the quasi-equilibrium group includes all nuclei above ^{16}O . Assuming that two ^{28}Si nuclei turn into one nucleus of the Fe-peak, one finds that the energy released by Si-melting is 0.2 MeV/nucleon or $\sim 2 \times 10^{17}$ erg/g.

Toward the end of Si-melting, all electromagnetic and strong nuclear interactions are in equilibrium with their inverses. Since neutrinos still escape freely from the stellar core, neutrino-producing weak interactions never come into equilibrium with their inverses and total equilibrium is not established. The last reactions to reach equilibrium are those linking ^{24}Mg – ^{20}Ne , ^{16}O – ^{12}C , and, finally, the reaction 3α – ^{12}C . When that happens, and assuming that all nuclides obey the statistics of an ideal Maxwell-Boltzman gas, Nuclear Statistical Equilibrium (NSE) is reached

and the composition is described as a function of three parameters: temperature T , density and electron fraction Y_e , or neutron excess η (in fact, Y_e and η are slowly modified under the action of weak interactions, specifically by electron captures).

In the conditions of NSE, for not too high temperatures ($T < 10$ GK), the most abundant nuclei are those with the largest binding energy for a given value of η . Thus, for $\eta \sim 0$, the most tightly bound nucleus is ^{56}Ni . Indeed, in *explosive nucleosynthesis*, ^{56}Ni is the dominant product of NSE; its radioactive decay has been (indirectly) observed in the case of the supernova SN1987A, brilliantly confirming the theory. However, in the quiescent burning conditions of late stellar evolution, weak interactions have time enough to modify η to values 0.06–0.08, corresponding to $Y_e \sim 0.46$ –0.47. In those conditions, the most tightly bound nucleus is the stable ^{56}Fe , while ^{52}Cr is also produced in substantial amounts (Fig. 3).

Explosive Nucleosynthesis in Supernovae

Explosive Nucleosynthesis in Core-Collapse Supernovae (CCSN)

When the composition of the stellar core becomes dominated by the strongly bound nuclei of the Fe-peak, the star has arrived at the end of its

quiescent life. Further contraction of the core and increase of its temperature cannot release nuclear energy to sustain internal pressure: reactions involving stable nuclei at the peak of the binding energy curve are endothermic and constitute sinks of thermal energy. Moreover, electron captures proceed at even higher rates and continue removing electrons from the stellar plasma, weakening the main source of resistance against gravity, namely electron pressure. The iron core collapses and the star dies in a spectacular supernova explosion.

Iron core collapse proceeds on a timescale of milliseconds. Due to increasingly high temperatures, photodisintegrations tear down Fe nuclei to nucleons and alpha particles, while higher densities favor electron captures and conversion of protons to neutrons. When the density of nuclear matter is reached ($\sim 10^{14}$ g cm $^{-3}$), the repulsive component of the strong nuclear force brings the collapse of the inner core abruptly to a halt. At the boundary of the inner core a shock wave is formed, with an energy approximately equal to the kinetic energy of the core at the moment of the bounce ($\sim 5 \times 10^{51}$ erg, according to results of numerical simulations). As the shock wave propagates outwards, into the still infalling *outer core*, it photodisintegrates its Fe nuclei (tearing them down to nucleons) and consequently loses ~ 8.8 MeV/nucleon or 1.5×10^{51} erg per $0.1 M_{\odot}$.

Nucleosynthesis, Stellar,

Fig. 3 Abundances of major nuclides in nuclear statistical equilibrium (NSE), as a function of the electron mole number Y_e

If the mass of the infalling outer core is $M_{OC} = M_{Fe} - M_{IC} < 0.4 M_{\odot}$, the shock can reach the base of the envelope with enough energy to launch a successful explosion. As the shock wave propagates through the stellar envelope, it heats the various layers to temperatures higher than in the corresponding central burning stages. It can be shown that the peak temperature $T_p(r)$ at radius r as a function of the kinetic energy of the shock (KE) may be written as

$$T_p(r) \sim 1.33 \times 10^{10} \left(\frac{KE}{10^{51} \text{ erg}} \right)^{1/4} \left(\frac{r}{10^8 \text{ cm}} \right)^{-3/4} \text{ K}$$

Stellar material in the layers hit by the shock wave is heated to those temperatures for a time of the order of the local hydrodynamic timescale $\tau_{HD} \sim 0.446 \rho_6^{-1/2}$ s, where ρ_6 is the mean density interior to radius r in 10^6 g cm^{-3} . If the nuclear burning timescale at radius r is smaller than the hydrodynamical timescale $\tau_{HD}(r)$, then *explosive nucleosynthesis* will take place, modifying the composition left from the previous quiescent burning stage. Taking into account the relatively steep density profiles of pre-supernova stars, it turns out that peak temperatures are sufficient for vigorous explosive Si- and O-burning. The Ne and C layers are less affected, while the He and H layers are not affected at all by the explosion (envelope densities are too low for explosive burning to take place in those layers).

The major reactions in explosive burning for a given fuel are the same as those of the corresponding quiescent burning. However, the beta decay lifetimes of unstable nuclei are often larger than the timescales of explosive nucleosynthesis τ_{nuc} . This implies that the cross sections of nuclear reactions on those unstable nuclei are also required, a situation that is not usually encountered in quiescent burning.

In general, one may distinguish three classes of elements/isotopes coming out of the explosion:

1. The first set (N, C, O, Ne, Mg) results mainly from hydrostatic He and C/Ne burning (layers not affected by explosive nucleosynthesis). The *yields* (ejected mass) of those elements

increase with stellar mass, following the sizes of the corresponding He- and C- exhausted cores. A comparison of those yields to observations provides indirect tests of the physics of the pre-supernova models.

2. The second group (Al, Si, S, Ar, Ca) includes elements produced in both hydrostatic and explosive burning. Their yields vary less with progenitor mass than the ones of the previous group. Comparison to observations tests both pre-supernova models and explosion energy.
3. The third set involves elements of the Fe-peak, produced essentially by explosive Si-burning. Their yields are highly uncertain at present, since they depend on the mechanism of the explosion, i.e., the shock wave energy, the various mixing processes, and the “mass-cut” (the dividing line between the mass of the star finally ejected and the one that falls back to the compact object).

Explosive Nucleosynthesis in Thermonuclear Supernovae (SNIa)

Another type of supernovae is the thermonuclear explosion of white dwarfs (WD) in binary systems (SNIa). As the WD accretes matter from its companion and its mass increases, compressional heating raises the internal temperature to several hundreds of MK. The high density of the WD ($\sim 10^9 \text{ g/cm}^3$) leads to a very efficient *screening* of the nuclear reactions, whereby repulsive Coulomb barriers between positively charged nuclei are lowered by the presence of negatively charged electrons. $^{12}\text{C} + ^{12}\text{C}$ fusion occurs then at considerably lower temperatures and at much higher rates than in massive stars. Ignition occurs when the $^{12}\text{C} + ^{12}\text{C}$ reaction releases energy faster than neutrino losses (mostly by plasma process) can carry it away.

Contrary to the case of normal stars (where perfect gas dominates the internal pressure), WD are composed of degenerate gas: internal pressure depends only on density, not on temperature. Thus, heating of the medium (through the energy released by $^{12}\text{C} + ^{12}\text{C}$) is not accompanied by pressure increase, which would lead to gas expansion and cooling; instead, temperature increases

steadily, and so does the $^{12}\text{C} + ^{12}\text{C}$ reaction rate. In those conditions, a “carbon deflagration” burns explosively the material of the star, all the way toward Nuclear Statistical Equilibrium (NSE). The timescale of the explosion is too short to allow for important electron captures, and thus the final outcome is essentially ^{56}Ni : about $0.7 M_{\odot}$ are produced (about half of the WD mass), as required by the observed luminosity of SNIa. Only in the central regions, the high densities favor the production of ^{54}Fe and ^{58}Ni through electron captures. In the outer layers, NSE is not reached because of lower temperatures that lead to the production of intermediate mass nuclei, like Si, Ca, etc.

From the point of view of galactic chemical evolution, SNIa play a very important role, since they produce between 50% and 65% of the Fe-peak nuclei. Their smaller frequency (they are ~ 5 times less frequent than CCSN) is compensated by the larger amounts of ^{56}Ni and Fe-peak nuclei produced by their explosion ($\sim 0.7 M_{\odot}$ of ^{56}Ni compared to $\sim 0.1 M_{\odot}$ on average for CCSN).

The Heavier Than Iron Nuclei

Nuclei heavier than those of the Fe-peak (henceforth called “heavy nuclei”) cannot be produced by charged particle reactions: the temperatures needed to overcome the high Coulomb barriers are such that photodisintegrations would tear down all nuclei to their constituent particles. The heavy nuclei rely on another mechanism for their formation: neutron captures on pre-existing “seed” nuclei.

Already in the early works of nucleosynthesis (Burbidge et al. 1957), it was recognized that two different types of neutron capture processes have contributed to the formation of heavy nuclei: the so-called s- (for *slow*) process, responsible for the formation of nuclei in the valley of nuclear stability; and the r- (for *rapid*) process, responsible for the synthesis of the most neutron-rich isotopes of heavy elements. The majority of the heavy nuclei have contributions from both the s- and ► **r-process**.

The s-Process

In the s-process, low neutron densities ($\sim 10^8 \text{ cm}^{-3}$) and rather long timescales (> 1 year) are involved, so that when an unstable nucleus (A, Z) is encountered along the s-process path, it has the time to decay into a stable isobar ($A, Z + 1$). Indeed, the lifetimes of most of the unstable nuclei close to the valley of stability range from a few seconds to less than a year and are lower than their lifetimes with respect to neutron captures in the above conditions. The neutron captures are *slow* with respect to beta decay, and thus the s-process path closely follows the bottom of the nuclear stability valley. Note that the s-process, by its very nature, cannot reach the heaviest nuclei (the long lived Th and U isotopes), which are separated from the heaviest stable nucleus (^{209}Bi) by more than 20 mass units.

The relevant physical conditions for this mechanism are the following: neutron densities $n_n \sim 10^8 \text{ cm}^{-3}$, temperatures $T \sim 150\text{--}300 \text{ MK}$, densities $\sim 2\text{--}100 \text{ g cm}^{-3}$, and timescales $\sim 10\text{--}1000$ year. These conditions correspond to the phase of quiescent He-burning. Two relevant sites have been identified:

1. Central He-burning in massive stars, where the neutron source is $^{22}\text{Ne}(\alpha, n)$; this reaction operates toward the end of He-burning, at $T \sim 250 \text{ MK}$. The number of neutrons released allows the synthesis of only nuclei in the mass range $60 < A < 90$ (the so-called “weak” component of the s-process). Part of those nuclei survive the advanced evolutionary phases of massive stars and are ejected in the interstellar medium by the final supernova explosion. From the theoretical point of view, the He-core s-process is quite robust (despite the uncertainties in the $^{22}\text{Ne}(\alpha, n)$ rate), but it lacks direct observational support.
2. Double shell (H- and He-) burning in low mass stars, evolving in the Asymptotic Giant Branch (AGB, running very close and parallel to the Red Giant branch). During the thermal pulse phase, protons from the H-shell are mixed in regions rich in α and ^{12}C . The coexistence of p, α , and ^{12}C allows the production of abundant neutrons through the reaction series

$p + {}^{12}\text{C} \rightarrow {}^{13}\text{N}$, which decays to ${}^{13}\text{C}$, followed by ${}^{13}\text{C}(\alpha, n){}^{16}\text{O}$. The recurring pulses allow the production of a large number of neutrons per seed Fe-nucleus and the synthesis of the “main component” of the s-process, i.e., nuclei with $90 < A < 210$. Between thermal pulses, the convective stellar envelope penetrates deep in the star and “dredges-up” material from the s-processed region to the surface, from where the strong AGB wind expels s-nuclei to the interstellar medium. This rather complex scenario is supported by observations of enhanced s-abundances in the surfaces of low mass AGB stars. However, the mixing of protons with material from the He-zones, as well as the 3d dredge-up, is poorly understood at present.

The r-Process

Contrary to the s-process, the r-process involves huge neutron densities ($>10^{20} \text{ cm}^{-3}$) for time-scales of the order of 1 s (obviously corresponding to an explosive site): neutron captures are so *rapid* with respect to beta decays that the r-process path drives the stellar material far to the neutron-rich side of the stability valley. This continues until the inverse reactions balance the neutron capture reactions. In the simplest picture of the r-process, an equilibrium is reached in each isotopic chain. In these conditions, a large amount of material is accumulated in unstable neutron-rich nuclides with “magic” neutron numbers (i.e., $N = 20, 50, 82$, etc.). Material slowly shifts to higher Z values through beta decays, which govern the speed of the nuclear flow along the r-process path. At the end of the neutron irradiation, all unstable nuclei β -decay toward the nuclear stability valley. The peak abundances in the r-process elements are obtained from the beta decay of very neutron-rich material “stored” in nuclei with “magic” neutron numbers during the r-process.

The site of the r-process is not yet identified, despite more than 30 years of intense investigation. Required neutron densities and timescales suggest an explosive event, while observations of the composition of the oldest stars in the Milky Way suggest that the r-nuclei were produced quite early on, i.e., that their source was short-lived. Core collapse SN satisfies both those

requirements, but neither the neutron source nor the relevant stellar layers have been identified yet. Neutron star collisions remain a plausible alternative.

Summary

The basic picture of stellar nucleosynthesis is well established nowadays, at least qualitatively. Massive stars ($M > 10 M_{\odot}$) synthesize in their various burning layers elements from C to Ca and eject them back to the interstellar medium in the final supernova explosion. During the explosion, a large fraction of Fe-peak isotopes (from Ti to Zn) is also produced. Intermediate mass stars ($2\text{--}10 M_{\odot}$) produce important amounts of He and CNO isotopes (except ${}^{16}\text{O}$, ${}^{18}\text{O}$, and ${}^{15}\text{N}$), as well as heavier than Fe-peak nuclei lying on the nuclear stability valley (s-nuclei, produced by neutron captures). All those nuclei are convected to the surface of the star and ejected into the interstellar medium through the stellar winds, mostly during the AGB and planetary nebula phases. The heavier than Fe-peak nuclei that are lying relatively away from the nuclear stability valley are thought to be produced during the explosions of massive stars, either in stellar layers exposed to large neutron fluxes (neutron-rich or r-nuclei) or in layers where photodisintegrations of already synthesized s-nuclei play an important role (proton rich or p-nuclei); the former process is also responsible for the formation of the heaviest stable nuclei, the Th and U isotopes. Finally, a large fraction of the Fe-peak nuclei ($>50\%$) is synthesized in thermonuclear supernovae (SNIa), white dwarfs in binary systems, that explode upon reaching the Chandrasekhar limit through accretion from a companion star (Fig. 4).

Taking into account the lifetimes (a few $10^6\text{--}10^7$ year for massive stars, a few $10^8\text{--}10^9$ year for intermediate mass stars and $>10^9$ year for the average SNIa), as well as the relative numbers of the various nucleosynthesis sites (the so-called Stellar Initial Mass Function, which favors the less massive stars), one may construct models of *Galactic chemical evolution* and compare their results to various observables.

Nucleosynthesis, Stellar, Fig. 4 Solar abundances and corresponding nucleosynthesis processes. The light elements are produced either in the Big Bang or through cosmic ray spallation reactions, while elements heavier

than B are produced in stars, either by fusion reactions (up to the Fe-peak) or by neutron captures (for heavier nuclei)

The success of this scenario lies mainly in its ability to reproduce (with reasonable assumptions) the solar distribution of intermediate mass elements (C to Fe-peak and s-elements). It also explains reasonably well most of the abundance ratios of such elements that are observed on the surfaces of stars of various ages in the Milky Way. Some important failures of our current understanding of stellar nucleosynthesis include the interpretation of observations of abundance ratios in the most metal poor stars of our Galaxy; this may point to significant variations from the “standard picture,” at least as far as the very first generations of massive stars are concerned (they could be more massive, on average, than today’s stars, or have larger rotation velocities). Progress is expected from continuous improvements in the fields of numerical simulations, nuclear data, and spectroscopic observations of abundances in all wavelengths.

The theory of stellar nucleosynthesis is certainly important to exobiology studies, to the extent that life (at least as we currently understand it) requires the presence of various heavy elements

(e.g., oxygen and carbon). However, a quantitative assessment of that requirement is difficult at present. Indeed, the absolute amount of heavy elements (i.e., their abundance with respect to H) that is required for the formation of telluric planets is very poorly constrained, either from theory or from observations. Observations of the [metallicity](#) distribution of stars with giant gaseous planets around them suggest that such stars are more Fe-rich on average than stars of the same spectral type not hosting planets. However, both observations and numerical simulations suggest that such a relation does not hold for telluric planets.

Definition

Nucleotides are glycosylated derivatives of purine and pyrimidine heterocyclic bases. The purine derivatives are adenine and guanine; the pyrimidine derivatives are ► [cytosine](#), uracil, and thymine (acronyms A,G,C,U,T), as shown in Fig. 1. Thymine occurs only as a deoxyribonucleotide and uracil only as a ribonucleotide. The bases form compounds termed nucleosides, or deoxynucleosides, by linking to a carbohydrate, ► [ribose](#), or 2-deoxyribose, respectively. In the case of a link to D-ribose (or to its 2'-deoxy form), a β -N-glycosidic bond is formed between the N⁹ of a purine or the N¹ of a pyrimidine and the anomeric carbon of the sugar. Nucleosides can

Nucleotide, Fig. 2 The nucleic base adenine bound to D-ribose yields the biologically predominant *anti*-adenosine conformer. In the *syn* conformation, the base is oppositely oriented about the N-glycosidic bond. The monophosphate nucleotide (5'AMP) is shown

be mono-, di-, or tri-phosphorylated yielding the corresponding nucleotides (Fig. 2).

Overview

Phosphorylation can occur at the 2', 3', or 5' positions and cyclic 2'–3' and 3'–5' nucleotides

may form, many of which play important biological functions. These compounds are commonly encountered in biological systems. Numerous alternatives and/or complex derivatives have been described both for the base and the sugar moieties, and for the number of phosphate groups.

Nucleotides are among the most important components of the cell and its metabolism, both in ► [anabolism](#) and catabolism. In addition to being the precursors of nucleic acids, nucleotides are allosteric effectors of enzyme activity, and thus exert numerous controls on enzymatic reactions. The major regulatory functions exerted often pertain to the pathways involved in the syntheses of the nucleotides themselves and to the reactions affording their precursors. Consequently, the pool of nucleotides in the cell is the result of strict anabolic equilibria.

The sophisticated compensatory mechanisms present at every level of the biological kingdoms are explained in evolutionary terms by their double role as providers of energy for phosphate transfer reactions and as genetic building blocks. In fact:

- Purine triphosphate nucleotides exert a particularly relevant role, GTP being an essential component of the translocation step in protein synthesis. (One GTP is used for the addition of one amino acid unit in protein polymerization from a tRNA-amino acid complex whose formation requires one ► [ATP](#).)
- The nucleotides ATP, GTP, CTP, TTP, and UTP are required in equilibrated concentrations for the polymerization of RNA and ► [DNA](#).
- ATP is the predominant energy store for phosphate transfer reactions.
- Nucleotides are constituents of key coenzymes (FAD, coenzyme A, NAD^+ , NADP^+) and are activated intermediates in important biosynthetic reactions, directly or in modified forms (such as S-adenosylmethionine and sugar-coupled nucleotides).
- Many nucleotide derivatives are metabolites which serve as alarmones, i.e., 3'–5' cyclic AMP (cAMP), ppGpp, pppGpp (guanosine tetra- and pentaphosphates), ApppA

(diadenosine tetraphosphate), and ZTP (5-amino 4-imidazole carboxamide riboside 5'-triphosphate). These compounds are in general formed under stress conditions such as the scarcity of a carbon source, amino acids, tRNA, or folate, or in the presence of oxidative stress, favoring alternative or escape metabolic responses.

Definition

In biology, Nucleus is a double-► [membrane](#) limited space in the eukaryotic ► [cell](#) containing

► [chromosomes](#) and nucleoli. The double membrane is perforated by the nuclear pores that allow the metabolic and genetic connection with the ► [cytoplasm](#). The outermost envelope is continuous with the endoplasmic reticulum. A cell may contain more than one nucleus (e.g., as a result of fusion of several cells – syncytium – or by nuclear division without cell separation, coenocyte). Some protists have two types of nuclei (macro- and micronucleus), and in the arachniophyta, there is the remnant of an ancient nucleus from an engulfed alga (nucleomorph). Albeit the evolutionary origin of the nucleus remains unsolved, several authors suggest that the nucleocytoplasm is the result of an ancient symbiotic association between a bacterial cell and an archaeal cell.

Definition

In chemistry and physics, the term nuclide refers to an atom with a distinct number of protons and neutrons in its nucleus. Nuclides may be stable or unstable. Of the ~3,100 known nuclides, there are ~256 that are so stable that they have never been observed to decay. Unstable nuclides are radioactive and are called radionuclides. Their daughter

decay products are called radiogenic nuclides. Nuclides with the same number of protons (of the same chemical element), but differing numbers of neutrons, are called isotopes.

Definition

Nulling ► [interferometry](#) is the name given to an instrumental technique based on interferences between several telescopes and aiming at detecting directly exoplanets. The principle is to create a virtual “blind spot” at the exact location of a bright source, a star, in order to reveal the much fainter source, which is a planet orbiting it.

Overview

This technique is a variant of ► [coronagraphy](#) and aims at reducing the extreme contrast of intensity that may exist between two objects very close one to the other, as a star-planet system, but here the solution lies in the interferometric recombination of radiation from several telescopes. Coronagraphy is used primarily in the visible and near infrared: the angular

resolution of a large telescope of say 10 meter diameter corrected by adaptive optics is indeed ten times better than the angle subtended by a planetary orbit of 1 AU at a distance of 10 pc; however, the star-planet contrast is extremely high (typically 10^{10} for the Sun-Earth system). On the other hand, in the mid-infrared ($\lambda = 5\text{--}20\ \mu\text{m}$), this contrast is much more favorable since it is around $10^{6\text{--}5}$. Furthermore, a set of biosignatures, complementary to those potentially observable in the visible, is found in this domain wavelength range: ozone (band at $9.7\ \mu\text{m}$), carbon dioxide, and water vapor. It has been suggested that the simultaneous presence of these three signatures may constitute strong evidence of the presence of life. However, an angular resolution of 0.1 arcsec at $\lambda = 15\ \mu\text{m}$ would require a telescope with a diameter exceeding 30 m which is not presently conceivable in space. The issue of blocking the glare from the star using several small telescopes found a solution with the proposal by Ronald Bracewell of black fringe interferometry (or nulling interferometry). The first step, illustrated in Fig. 1, is to produce interference fringes projected onto the

sky by interferometric recombination of radiation from two telescopes separated by a distance D . The fringes alternatively transmit and block the light, so, if it is arranged that the star is put on a dark fringe and that half the inter-fringe spacing corresponds to the distance separating the star from the putative planet, then the contrast is optimal. In a conventional interferometer, only the bright central fringe, which corresponds to a zero path difference, is common to all wavelengths, while the fringe systems at different wavelengths overlap each other, leading to a global blurring and no actual dark fringe. On the other hand, it is unthinkable to operate a nulling interferometer at a unique wavelength to detect an exoplanet, because the planet's brightness is extremely low and, in addition, the needed spectral information is in a wide wavelength range ($5\text{--}17\ \mu\text{m}$). The powerful idea proposed by Bracewell was to insert an optical phase shift of π , not dependent on the wavelength and thus said to be achromatic, in one arm of the interferometer: the central fringe becomes a dark one but is still common to all wavelengths. Putting the star on this fringe then leads in

Nulling Interferometry, Fig. 1 The principle of nulling interferometry. *Left:* the optical scheme. The light collected by two telescopes pointing in the same direction is recombined after an optical device (in blue) has introduced a phase shift of π on one arm of the recombination path. The resulting interference pattern is characterized by a central fringe, which is dark and not bright as in a

conventional interferometer. *Right:* the fringe pattern. This is in fact a transmission map projected onto the sky. If the star (yellow) is put on the central dark fringe, it is masked, while the fringes' separation can be adjusted (by changing the telescopes separation), so as to correspond to a maximum of transmission at the location of the planet (red)

principle to an efficient rejection of its light without a limitation in spectral band.

Basic Methodology

Designing a nulling interferometer supposes that the beams from two or more large telescopes, separated by a distance of at least 50 m, are recombined coherently and that a special device, called an *achromatic phase shifter*, is introduced in one or several of the beams before recombination. In addition, since the expected brightness of the exoplanet is extremely low, the usually strong thermal background that characterizes observations in the infrared has to be maximally reduced: this means that the telescopes must be at a very low temperature, typically below 100 K. If we add that the atmosphere absorbs a large part of the useful wavelength range, one understands that the space environment is in practice mandatory. Finally, a very precise control of wavefront defects and a precise matching of the interferometer arms are required to achieve the required null depth of 10^{-5} . For all those reasons, it appears that detecting and characterizing exoplanets using nulling interferometry from space is an extremely ambitious goal and will not come to fruition before probably one or two decades.

Note that the measured signal is not only the sum of that from the planet(s) and some residual light from the star. There is also light corresponding to starlight scattered by the dusty disk of micron-sized particles, the remnants of the protoplanetary disk around the star. This disk is a powerful source of emission, the so-called *exozodi* light (derived from the name *zodiacal light* used for the solar system), which may be well above the emission from the planets. To distinguish the fraction of radiation specific to the planet, one can modulate its signal. Bracewell proposed to rotate the interferometer around the line of sight: the image of the planet then travels on the system of fringes projected onto the sky, becoming sometimes visible, sometimes extinct, so that only the signal modulated at the rotation frequency and consistent with the expected pattern reflects the contribution of the planet.

Key Research Findings

Several difficulties emerged when the study of nulling interferometers became more detailed.

- First, the angular size of the star is not infinitely small and photons at the edge of the stellar disk can escape the nulling. They represent only a tiny fraction of the starlight, but the contrast planet/star is so small that they are still predominant and the corresponding noise becomes a limitation. It may be shown that using more than two telescopes can overcome this limit.
- Second is how does one achieve the achromatic phase shift of π . Several solutions with good performances have been demonstrated in the laboratory: sets of transparent blades in each arm of the interferometer with proper materials and thicknesses, use of symmetrical pairs of periscopes, crossing of a focus in one arm, use of specific checkerboard mirrors, use of light dispersion on a deformable mirror, etc.
- Third, the signatures between a planet and the exozodi seen partly edge-on (appearing thus elliptic) must be separated: the modulation by a simple system of fringes would be undistinguishable. With a smart choice of interferometer configuration, one can, however, distinguish the modulated signal produced by a single object from the one due to a centrosymmetric structure such as the exozodi.
- Fourth, the cancelation of the stellar flux must have great temporal stability. This is, perhaps, the most serious difficulty: any deviation, even very small, from the π phase shift produces very large fluctuations in the starlight leakage, introducing an extra noise. This point is subject to particular attention in the laboratory experiments.
- Fifth, the free-flying interferometer concept should be evaluated. A nulling interferometer aiming at exoplanet detection is meaningful only in space, but the size of the baseline, larger than 30 m, makes unbelievable a system where telescopes would be physically connected. The concept which is being studied

Nulling Interferometry,

Fig. 2 Artist's view of the most recent concept of the Darwin project studied by ESA and NASA. The arrangement of the four telescopes in an X pattern allows modulation in a special way of the light from the planet, so that it may be distinguished from the light emitted by a cloud of small particles (the exozodiacal disk) in the plane of the planetary system; this cloud is believed to surpass the planet's brightness by a large factor

is one of several free-flying crafts, each carrying a telescope, plus one carrying the recombination station, with distances between them made constant through some servo-system using micro jet engines and micrometric distance measurement. The Darwin mission concept is based on this idea (Fig. 2).

Applications

The main goal of this technique, which will take many years to reach an appropriate technology readiness level, is the detection and characterization of objects analogous to the Earth, that is, small exoplanets in the ► [habitable zone](#), and ultimately to detect the presence of life. The Darwin mission (Fig. 2) is the emblematic project, submitted in 2009 to space agencies but not selected, which illustrates the best state of the art in terms of specific studies carried out over several years. The present concept relies on four cryogenic telescopes of 1 m diameter, arranged on an X-shaped pattern, and a recombining station which is at the common focus of the telescopes, avoiding thus the use of the complex delay lines usually found in interferometers. The distance between telescopes can be changed and a clever

phase modulation allows astronomers to distinguish the contribution of a planet from the one of exozodi.

Another goal that appeared more recently is the possibility to use a nulling interferometer from the ground to detect the exozodi in several stars, this knowledge being important for preparing future space missions. Several experiments have been developed in that direction at the Keck and the LBT telescopes in the USA.

Future Directions

During the previous decade, a vigorous program of research and development has been put in place, especially in the USA and in Europe, in order to find the most appropriate solutions to the various technical problems listed above. For several of them, the performance level reached in the laboratory proves that there should be no definitive technical blockade; however, it must be clear that the road will be a long one before a nulling interferometer mission can be actually launched; this may be the reason why today, nulling interferometry is no longer considered by space agencies as a potential mission for their midterm program.

DON	Dissolved organic nitrogen
POM	Particulate organic matter

Definition

Nutrients required for life (carbon, nitrogen, phosphorus, and certain trace metals, such as iron, zinc, and cobalt) are cycled throughout the ocean as they are incorporated into biomass, then released and recycled upon cell lysis through the microbial loop, or consumed and transferred to higher trophic levels, until delivered as fecal matter to the deep ocean through the biological pump.

Overview

Most biological production occurs in the surface ocean within the photic zone (where light reaches to about 100 m) and is limited by the availability of light and nutrients. Single-celled phytoplankton fix carbon through photosynthesis, forming the basis of the marine food web. In one commonly used example, photosynthesis and associated reactions can combine water, inorganic carbon (carbon dioxide; CO₂), nitrogen (nitrate; NO₃[−]), and phosphorus (phosphate; PO₄^{3−}) to form organic matter and release oxygen, in the following proportions (Sarmiento and Gruber 2006):

Mineralization (i.e., respiration, remineralization, oxidation of organic matter, etc.) is the opposite of this reaction, using oxygen in seawater as an electron acceptor to decompose organic matter and produce inorganic carbon (C), nitrogen (N), and phosphorus (P) while releasing energy. The stoichiometric relationship of C:N:P in phytoplankton of 106:16:1 is the “Redfield ratio” (Redfield 1958), but more recent research showed that this relationship varies based on phytoplankton community structure and available nutrients (Canfield et al. 2005).

Basic Methodology

Nutrients and trace metals in the ocean are studied from samples typically collected from research vessels, often using a rosette of bottles that trap water from specified depths. Concentrations are measured using nutrient analyzers and ICP-MS (inductively coupled plasma mass spectrometry). Productivity (carbon fixation rates) can be directly measured using CO_2/O_2 consumption or production. Rates of transfer from one form to another are typically determined using isotopic tracers (stable isotopes such as ^{13}C or ^{15}N or radioisotopes such as ^{14}C) or variation in natural abundance of stable isotopes measured using isotope ratio mass spectrometry (IRMS). Mathematical models are used to scale results. Biogeochemical transformation rate measurements are often paired with functional gene abundance or transcriptomes to link structure and function.

Key Research Findings

Carbon

The C in living biomass represents a small fraction of the total C inventory on Earth (0.002%; Canfield et al. 2005). The majority of C in the ocean is inorganic or within the DOM. Carbon enters the atmosphere as CO_2 and the ocean as HCO_3^- . Atmospheric CO_2 equilibrates with the

carbonate system of the ocean (Sarmiento and Gruber 2006), coupling these two pools.

The ocean is a net sink for atmospheric C ($\sim 2.6 \pm 0.5 \text{ GtC yr}^{-1}$; Le Quéré et al. 2015) through photosynthesis by phytoplankton. Abundant eukaryotic phytoplankton include diatoms (Bacillariophyceae) and coccolithophorids (Prymnesiophyceae), which often dominate coastal and upwelling areas. Diatoms are estimated to be responsible for $\sim 20\%$ of annual global CO_2 fixation (Matsuda et al. 2017). Prokaryotic picoplankton, specifically *Prochlorococcus* and *Synechococcus*, are the dominant primary producers in low-nutrient, open-ocean regimes (Moore et al. 2002). Zooplankton graze on phytoplankton, and their fecal pellets aggregate and fall to the ocean bottom. Viruses lyse phytoplankton and drive organic C from the particulate to dissolved pools via the *viral shunt* (Wilhelm and Suttle 1999). Heterotrophic bacteria remineralize fecal pellets, as well as other POM and DOM, to bioavailable inorganic nutrients (Ducklow et al. 2001). To complete the *biological pump*, respiration by consumers in surface waters converts organic C back to CO_2 and releases it to the atmosphere (Ducklow et al. 2001). Below 1000 m depth, dissolved organic C (DOC) is respired back to CO_2 and remains in the deep oceans, causing CO_2 enrichment. CO_2 can remain in the deep ocean for $>1,000$ years before it returns to the surface. Without biological production, atmospheric CO_2 would rise by >200 ppm (Sarmiento and Gruber 2006).

DOM is the largest constituent of the detritus pool in the ocean. Phytoplankton exudates are probably the most important DOM source in the photic zone (Canfield et al. 2005). Ogawa and Tanoue (2003) estimate that the marine DOC reservoir is 700 Gt, comprised of 650 Gt of refractory and 50 Gt of semi-labile DOC, roughly equivalent to the size of the atmospheric CO_2 pool (750 Gt). DOM dynamics are poorly understood due to the difficulty in characterizing complex organic compounds. Less than 20% of DOM has been grouped into major biological macromolecules, such as carbohydrates, amino acids, and lipids, while recalcitrant humic compounds comprise 15–25% of marine DOM (Canfield et al. 2005).

Heterotrophic microbes are the primary consumers of marine DOC and preferentially use specific components of the bulk DOC pool (Sarmiento et al. 2013). In the *microbial loop* (Azam et al. 1983), a large fraction of primary productivity is released as DOM and used by microbes; predatory protists consume bacteria and are then grazed by larger zooplankton or remineralize DOM to inorganic nutrients, which are assimilated by phytoplankton, then grazed by microzooplankton, and so on. However, microbes may alter the chemical composition of DOM, resulting in changing C:N:P ratios (and other elements), creating increasingly recalcitrant DOM via the *microbial C pump* (Jiao et al. 2011). The average turnover time for oceanic DOM is 30–300 years, but turnover time for labile DOM in the euphotic zone is <10 years, while recalcitrant DOM persists for 4000–8000 years in the deep ocean (Jiao et al. 2011; Canfield et al. 2005). Thus, production of recalcitrant DOM (within the microbial loop) is an important mechanism for long-term marine sequestration of fixed atmospheric C.

Nitrogen

Nitrogen is the limiting nutrient in much of the surface ocean, although lack of adequate iron (Martin and Fitzwater 1988) and light (Mitchell et al. 1991) also limits primary productivity in some regions. Nitrogen species with a range of oxidation states are found in the ocean, from +5 (NO_3^-) to −3 (NH_4^+). The most abundant species, dinitrogen (N_2) gas, saturates the water column and is not “fixed” or bioavailable, except to diazotrophs. Because bioavailable N usually limits oceanic primary production, N availability also controls CO_2 removal from the atmosphere. During diazotrophy (N fixation), N_2 is converted to NH_4^+ and incorporated into biomass, which can be remineralized to NH_4^+ during decomposition (Capone and Carpenter 1982). NH_4^+ may then be assimilated by primary producers or converted to NO_2^- , and then NO_3^- , via nitrification (Ward 2008). Dissimilatory NO_3^- reduction to NH_4^+ (DNRA) converts NO_3^- to NO_2^- , then to NH_4^+ (Tiedje 1988). Anammox (anaerobic NH_4^+ oxidation) transforms NH_4^+ and NO_2^- to N_2 gas

(Mulder et al. 1995). In canonical denitrification, NO_3^- is first converted to NO_2^- , then to NO and N_2O , and finally to N_2 gas (Zumft 1997). DNRA, anammox, and denitrification occur in anaerobic areas of water column oxygen minimum zones (OMZs) or anoxic sediments.

The nitrification pathway converts ammonia to NO_2^- and, subsequently, NO_3^- via two separate processes performed by mutually exclusive groups of organisms (ammonia oxidizers and NO_2^- oxidizers) or within a single organism (comammox; Pinto et al. 2016). The ammonia (NH_3)-oxidizing archaea (AOA) are the dominant group of NH_3 oxidizers in the ocean and are primarily comprised of *Crenarchaeota* or *Thaumarchaeota* (Ward 2008). Taxonomically, the NH_3 -oxidizing bacteria (AOB) fall into two proteobacterial classes, either the *Betaproteobacteria*, including the genera *Nitrosomonas*, *Nitrospira*, and *Nitrosovibrio*, or the *Gammaproteobacteria*, including the genera *Nitrosococcus* (Ward 2008). NO_2^- oxidizers are primarily *Nitrospinae* and *Nitrococcus* (Hofer 2017). At oxic-anoxic boundaries, coupled nitrification-denitrification is the “opposite” of N_2 fixation in that bioavailable N is removed as N_2 , and the balance between these pathways controls the inventory of fixed N in the ocean.

In the absence of oxygen, denitrifying bacteria use NO_3^- as an electron acceptor for the oxidation of organic matter:

Denitrification occurs in sediments and anoxic parts of the water column (Devol 2008), although a source of organic carbon is also required. Canonical denitrification is the heterotrophic, respiratory, stepwise reduction from NO_3^- to N_2 , in which the penultimate step is the production of N_2O , a potent greenhouse gas that can also be released. Denitrifiers encompass a wide diversity of organisms, from subgroups of proteobacteria to archaea (Zumft 1997) to foraminifera (Risgaard-Petersen et al. 2006).

Anammox, posited for decades, was confirmed in a Dutch wastewater treatment plant (Mulder

et al. 1995). Anammox is a useful pathway for wastewater treatment because it removes NO_2^- and NH_4^+ in equal proportions under anoxic conditions to produce N_2 :

Anammox bacteria belong only to the phylum *Planctomycetes*, and four genera have been identified: *Candidatus* Kuenenia, *Candidatus* Brocadia, *Candidatus* Anammoxoglobus, and *Candidatus* Scalindua (review by Harhangi et al. 2012). The anammox bacteria are slow-growing autotrophs, and recent measurements of anammox rates have shown it to be an important N loss pathway in the ocean (Devol 2008), contributing ~28% of total N loss (Babbin et al. 2014). The only clade of anammox bacteria identified in the Arabian Sea and many other marine environments, however, is *Scalindua* (Harhangi et al. 2012), suggesting that anammox diversity is limited in the marine environment.

Most water column N loss occurs in the three major OMZs, which together account for less than half of total fixed N loss in the ocean (Devol 2008). The three major OMZs are in the eastern tropical north Pacific off the coast of Mexico (the largest OMZ by area), the eastern tropical south Pacific off of the coasts of Peru and Chile, and the northern Arabian Sea (the largest OMZ by volume).

Phosphorus

Phosphorus is also a critical element for life, required for nucleic acids (DNA and RNA), energy storage and transfer (NADPH and ATP), and cell membranes (phospholipids). The P cycle differs from the N and C cycles in that it has no gaseous phase and is not involved in redox cycling. While P has four oxidation states (−3, 0, +3, +5), only the +5 state is stable under natural conditions in aqueous solutions. The main source of P to the oceans is riverine runoff from terrestrial weathering (Benitez-Nelson 2000), as dissolved PO_4^{3-} and organic forms. Upwelling, vertical advection, and eddy diffusion also supply P (and N) from the deep ocean and can fuel primary production in the euphotic zone. The only natural

P removal mechanism from the oceans is burial within marine sediments.

A deficit for N (compared to Redfield 16:1) is often observed in the subsurface supply of dissolved N and P, and cellular C:N is more constrained than the C:P (and hence N:P) ratio (Sarmiento and Gruber 2006). Thus, N is typically the limiting nutrient in the open ocean. However, P is generally considered the ultimate limiting nutrient for primary productivity on geological timescales (Poulton 2017), driven by permanent burial and terrestrial weathering rates. Under anoxic conditions, surface sediments can sequester P through binding to Fe(III), forming an “iron cap.” However, if weathering rates increase, thus increasing the oceanic P inventory, the N inventory could be increased via promotion of N fixation.

Low PO_4^{3-} (<0.1 μM) and elevated dissolved organic P (DOP; >0.2 μM) concentrations are typically observed in the euphotic zone, but below this depth, PO_4^{3-} and DOP concentrations reverse, with gradually increasing PO_4^{3-} and decreasing DOP to 1000 m (>3 μM DIP and <0.1 μM DOP; Loh and Bauer 2000). Phytoplankton uptake and assimilation in the photic zone, switching to respiration and remineralization with depth, drives this general pattern. When PO_4^{3-} concentrations are low, microbes exude extracellular enzymes to break down more complex, organically bound P to PO_4^{3-} (Goldammer et al. 2011). Typically, less than 10% of assimilated P is exported from the euphotic zone (Karl and Bjorkman 2002).

Trace Elements

Biological life requires a multitude of other elements at low concentrations (“trace” elements), including metals, such as zinc (Zn), cobalt (Co), and iron (Fe). Of these, Fe is of particular interest in that its chemistry results in free Fe becoming biologically unavailable in seawater, leading to Fe limitation of primary production for up to 25% of global ocean surface waters (de Baar et al. 2005). Observations and experiments have confirmed this observation on multiple scales (Martin and Fitzwater 1988; Boyd and Ellwood 2010). Although the requirement for Fe across

biological life remains constant, cellular quotas can vary by an order of magnitude, depending on Fe availability (Wilhelm et al. 2013).

The marine Fe cycle has been studied extensively for decades, focusing primarily on the role of Fe in limiting primary production (Boyd and Ellwood 2010) and the roles of microbial communities (Strzepek et al. 2005) and viruses (Poorvin et al. 2004) in Fe mineralization. Iron is commonly chelated to organic compounds (*ligands*) in seawater (de Baar et al. 2005), and this metal-ligand interaction may control the biological availability of Fe to the plankton community.

Future Directions

Understanding how marine organisms interact with their environment (i.e., nutrients) and in turn how competition for these nutrients drives different populations remains an overarching challenge for the marine community. All of this is couched within the background of changing climate – both temperature and oceanic pH are likely to alter the relationships nutrients and organisms have, and these remain a moving target.

Acronyms

NGB

Synonyms

Nuvvuagittuq Supracrustal Belt; Porpoise Cove Greenstone Belt

Definition

The Nuvvuagittuq greenstone belt is ~10 km² volcano-sedimentary sequence located in North-eastern Canada. The belt is mostly composed of mafic metavolcanic rocks comprising chemical sedimentary rocks that are interpreted to have recorded traces of early life. These supracrustal rocks are at least 3.8 billion years old, but deficit in ¹⁴²Nd compared to the modern terrestrial Nd standard in the metavolcanic rocks suggests they were formed 4.3 billion years ago. This would make them the oldest rocks known on the Earth and hosting the earliest evidence of life on our planet.

History

The NGB was first studied in the 1960s (Lee 1965), but it is only since the early 2000s that it

became a region of interest for early Earth and early life research, with the discovery of its ancient age. The first geochronological data showing that the belt is the oldest component of the Northeastern Superior Province was acquired during an MSc thesis focusing on the structural investigation of the Nuvvuagittuq area (Nadeau 2003), in collaboration with the Geological Survey of the Province of Quebec (Ministère de l'Énergie et des Ressources naturelles du Québec), conducting regional scale mapping of the Northeastern Superior Province of Canada (Simard et al. 2003; Simard 2008). Zircons from a thin felsic trondhjemitic band within the NGB supracrustal rocks yielded a U-Pb upper intercept age of 3825 ± 16 Ma (David et al. 2003; Simard et al. 2003). Similar Eoarchean U-Pb ages on zircons from the same lithology were subsequently obtained (Cates and Mojzsis 2007; David et al. 2009; Darling et al. 2013; O'Neil et al. 2013; Augland and David 2015), confirming the age of >3.75 Ga for the NGB. Because the NGB mostly includes mafic rocks that rarely contain the zircons used for conventional U-Pb ages, the age of the NGB supracrustal rocks was essentially constrained from the rare zircon-bearing trondhjemitic bands, providing a minimum age given their intrusive relationship to the mafic metavolcanic rocks of the NGB. The discovery of ¹⁴²Nd deficits compared to the modern terrestrial standard and the correlation between the ¹⁴²Nd/¹⁴⁴Nd and Sm/Nd ratios of the metavolcanic rocks and co-genetic ultramafic cumulates has subsequently been used to suggest an even older Hadean age of ~4.3 Ga for the NGB (O'Neil et al. 2008). This would make the NGB metavolcanic rocks the oldest rocks preserved on Earth. The interpretation of the ¹⁴²Nd isotopic composition of the NGB rocks and their Hadean age is not unanimously accepted in the scientific community, but all acknowledge that it is at least ~3.8 Ga. Given the existence of only a handful of areas containing rocks older than 3.7 Ga, and the possibility that the NGB represents the only known remnant of Hadean oceanic crust, it has become a region of high interest for early Earth

research and to study the origin of life on Earth. Dodd et al. (2017) have in fact proposed that the NGB banded iron formation hosts the earliest evidence of biological activity on Earth.

Overview

The Nuvvuagittuq greenstone belt (NGB) is located in the Northeastern Superior Province of Canada, approximately 35 km south of the Inuit municipality of Inukjuak on the east coast of Hudson Bay. The Nuvvuagittuq greenstone belt covers an area of ~10 km² and is composed of a volcano-sedimentary sequence at least Eoarchean in age (Cates and Mojzsis 2007), comprising rocks that may have been formed 4.3 billion years ago (Ga), which would make them the oldest rocks known on the Earth (O'Neil et al. 2008, 2012). The geochemistry of the Nuvvuagittuq metavolcanic rocks suggests that they represent a remnant of hydrothermally altered oceanic crust (O'Neil et al. 2019). Hematite structures found in the Nuvvuagittuq banded iron formations are interpreted to represent the oldest trace of biological activity of Earth (Dodd et al. 2017), pushing back the appearance of life to at least another 100 million years and perhaps more than 500 million years.

The Geology of the Nuvvuagittuq Greenstone Belt

The Nuvvuagittuq greenstone belt has experienced multiple phases of deformation and is now isoclinally folded into a north plunging synform and then refolded into an open south-plunging antiform (O'Neil et al. 2007; David et al. 2009). Most of the belt has been metamorphosed to at least upper amphibolite facies conditions (O'Neil et al. 2007; Cates and Mojzsis 2009), but greenschist facies metamorphic assemblages of the metavolcanic rocks in the southwestern and southeastern corners of the NGB suggest that some areas may not have reached the same high temperature as the rest of the NGB or that they represent retrogressive assemblages (O'Neil et al. 2011, 2019). These lower grade rocks locally preserve deformed pillow lava structures (O'Neil et al. 2011), consistent with their

formation in an oceanic environment. The NGB is directly surrounded and intruded by Eoarchean to Paleoproterozoic felsic rocks from the tonalite-trondhjemite-granodiorite (TTG) series and intruded by late Neoproterozoic granitic pegmatites (Cates and Mojzsis 2007, David et al. 2009; O'Neil et al. 2013).

The dominant lithology of the NGB is a heterogeneous amphibolite composed of variable proportions of cummingtonite + biotite + quartz, ± plagioclase ± garnet ± anthophyllite ± cordierite. Despite the mineralogical variations, these mafic metavolcanic rocks share recognizable petrological and geochemical characteristics and are grouped into a lithostratigraphic unit called the Ujaraaluk unit (O'Neil et al. 2011, 2019), formerly called “faux-amphibolite” (O'Neil et al. 2007). The proportion of cummingtonite and biotite in the Ujaraaluk unit varies widely, with lithologies ranging from amphibolite composed almost entirely of cummingtonite, to garnet-biotite schist. Variations in the proportions of cummingtonite and biotite also occur on a centimeter-scale. The amount of garnet is also highly variable ranging from garnet-free assemblages to rocks containing a significant proportion of garnet (up to ~15%). Locally, the Ujaraaluk unit is characterized by a Mg-rich and Ca-poor assemblage of cordierite, anthophyllite, and biotite. This cordierite-anthophyllite assemblage is interpreted to result from hydrothermal seawater alteration of oceanic crust (O'Neil et al. 2019).

The Ujaraaluk unit is generally basaltic to basaltic andesite in composition but can be divided into high-Ti and low-Ti units, following distinct fractionation trends for their incompatible trace elements. The low-Ti Ujaraaluk is further subdivided into depleted low-Ti Ujaraaluk and enriched low-Ti Ujaraaluk, according to relative concentrations in incompatible trace elements. The three Ujaraaluk groups display distinct Al/Ti ratios and characteristically different incompatible trace element profiles. They also follow a chemostratigraphy within the NGB with the high-Ti Ujaraaluk at the base of the sequence, the depleted low-Ti Ujaraaluk stratigraphically above the high-Ti group, and the enriched low-Ti Ujaraaluk group at the very top of the sequence (O'Neil et al. 2011).

The boundary between the high-Ti and a low-Ti Ujaraaluk unit is marked by the occurrence of a banded iron formation (BIF) 5–30 meters in width that can be traced continuously along the western limb of the belt and discontinuously along the eastern limb. The BIF is essentially a finely laminated quartz + magnetite + grunerite rock. A large silica-formation occurs in the eastern limb of the belt that reaches 100 meters in width. It is composed almost entirely of massive recrystallized quartz with minor disseminated pyrite. At the southern-most edge of this limb, the silica-formation grades into BIF, suggesting that it may be a silica-rich facies of the BIF. Within the lower metamorphic grade assemblages, the BIF occurs as a laminated jasper BIF sometimes associated with ferruginous carbonate rocks (Dodd et al. 2017). The jasper BIF and ferruginous carbonate rocks include microscopic structures such as concentric mineral rosettes, coarse-grained sub-millimeter granules and fine microscopic laminations, ribbons, tubes, and filaments of nanoscopic hematite in chert, which have been interpreted as likely derived from an ancient microbial ecosystem (Dodd et al. 2017). This would constitute one of the earliest, if not the earliest, evidence of biological activity on Earth.

Geochronology of the Nuvvuagittuq Greenstone Belt

The age of the NGB has been highly debated. The only scientific consensus is that the NGB is at least ~3.8 Ga, evidenced by U-Pb ages on zircons from thin trondhjemitic bands intruding the Ujaraaluk unit (Cates and Mojzsis 2007, David et al. 2009, Darling et al. 2013; O'Neil et al. 2013). A maximum age of 3780 Ma has been proposed for the NGB, based on U-Pb ages on a few zircons from rocks interpreted as detrital fuchsite-bearing quartzite, which would impose a maximum age of deposition for the volcano-sedimentary package (Cates et al. 2013). The fuchsitic quartzites have however been interpreted as highly metasomatized felsic intrusive rocks by Darling et al. (2013) which would thus place only a minimum age on the NGB mafic volcanic rocks.

Rocks from the Ujaraaluk unit display a wide variation in $^{142}\text{Nd}/^{144}\text{Nd}$ ratios (O'Neil et al. 2008, 2012). Given the half-life of 103 million years of ^{146}Sm , variations in ^{142}Nd can only be produced by Sm-Nd fractionation prior to ~4.0 Ga. The correlation between Sm/Nd and $^{142}\text{Nd}/^{144}\text{Nd}$ ratios measured in all geochemical groups of the Ujaraaluk unit and co-genetic ultramafic cumulates would be consistent with an age of ~4.3 Ga for these rocks (O'Neil et al. 2008, 2012, 2019), which would make them the oldest known rocks on the Earth. This interpretation for the variation in $^{142}\text{Nd}/^{144}\text{Nd}$ ratios has been challenged and rather attributed to mixing with an enriched Hadean source (Roth et al. 2013; Caro et al. 2017), but a ^{147}Sm - ^{143}Nd whole-rock isochron obtained on differentiated gabbroic sills intruding the Ujaraaluk unit and giving an age of 4.1 Ga would support an Hadean age for the NGB (O'Neil et al. 2012, 2019).

Significance for Early Earth Environments

Rocks from the Ujaraaluk unit generally have a mafic composition, and, prior to metamorphism, would range from basalt to andesite in terms of their silica contents ($\text{SiO}_2 = 42\text{--}67$ wt.%). The high-Ti Ujaraaluk unit at the base of the NGB has geochemical features that resemble those of tholeiitic volcanic suites, whereas the low-Ti Ujaraaluk rocks at the top of the sequence exhibits a wider range of composition from basalt to andesite and is characterized by a chemical composition similar to modern boninites and calc-alkaline volcanic suites (Turner et al. 2014; O'Neil et al. 2016). This succession of volcanic rocks displaying tholeiitic, to boninitic, to calc-alkaline affinities, is reminiscent of supra-subduction environments, which suggests that the NGB metavolcanic rocks may have been formed in subduction initiation settings in the Eoarchean or perhaps in the Hadean (Turner et al. 2014; O'Neil et al. 2016).

The geochemistry of the cordierite-anthophyllite assemblage of the Ujaraaluk unit, with high Mg and low Ca contents, is consistent with its protolith being basaltic to andesitic volcanic rocks hydrothermally altered by seawater, similar to volcanogenic massive sulfide deposits

hydrothermal environments (O'Neil et al. 2019). The presence of a potentially 4.3 Ga banded iron formation within the Nuvvuagittuq greenstone belt could have a significant impact on the study of the timing of the origin of life on Earth. Although the causes of Fe precipitation throughout geologic time are poorly understood, the BIF that occurs in Archean greenstone belts must have been precipitated under anoxic conditions. It has been suggested that Fe^{2+} can be directly oxidized by microbial activity under anaerobic conditions (Lovley et al. 1987; Widdel et al. 1993). Konhauser et al. (2002) have even proposed that Archean BIF could have been precipitated by the activity of anoxic bacteria. However, establishing the chemical sedimentary origin for a rock is a prerequisite to demonstrating potential biological activity involved in its formation. The trace element chemistry of the NGB BIF is consistent with a marine exhalite origin with a distinct seawater signature (O'Neil et al. 2007). The NGB BIF has heavier Fe isotopic compositions than the surrounding igneous lithologies (Dauphas et al. 2007; O'Neil et al. 2007), a feature that is consistent with an origin as a chemical precipitate. The sedimentary origin for the NGB BIF is also supported by the mass-independent fractionation of sulfur isotopes (Thomassot et al. 2015) and by their REE + Y geochemical compositions, displaying light rare earth element depletion relative to heavy rare earth element, with La and Eu positive anomalies (Mloszewska et al. 2012), typical of Archean BIF precipitated from seawater (Bolhar et al. 2004). High $\delta^{18}\text{O}$ (8–12‰) and $\Delta^{17}\text{O}$ (−0.02 to −0.05) values measured in the NGB metavolcanic rocks support the fact that they represent a section of ancient oceanic crust hydrothermally altered at low-temperature by seawater and perhaps accompanied by silicification between 50–150 °C (Bindeman and O'Neil 2022). The NGB BIF thus represents the ideal candidate to address the controversial question of the timing of the origin of life on Earth. The NGB jasper BIF includes micrometer-scale hematite tubes and filaments with morphologies and mineral assemblages similar to those formed by of microorganisms in modern hydrothermal vent precipitates (Dodd et al. 2017). The comparison between the features observed in the NGB BIF and analogous microfossils in younger rocks suggests that

biological activity in submarine-hydrothermal environments occurred at least at 3.8 Ga, and perhaps as early as 4.3 Ga.

Key Research Findings

The mafic metavolcanic rocks of the Nuvvuagittuq greenstone belt are interpreted to represent a remnant of hydrothermally altered oceanic crust, at least Eoarchean in age and possibly as old as 4.3 Ga, which would make them the oldest rocks discovered to date on Earth. The geochemistry of these rocks suggests they represent volcanic rocks formed in a subduction initiation setting. The geochemical and isotopic composition of the banded iron formation is consistent with sediments precipitated from seawater. The microscopic structures preserved in the jasper banded iron formation potentially suggest microbial activity in the Hadean.

Definition

The O/OREOS (Organism/Organic Exposure to Orbital Stresses) nanosatellite is a 5.5-kg,

10 × 10 × 34 cm free-flying autonomous spacecraft that comprises a control, power, and communications “bus” that supports two separate “1U” (10-cm cube) experimental astrobiology payloads. The 3U O/OREOS spacecraft launched as a secondary payload in November 2010 to a 650-km circular orbit and successfully completed its primary mission 6 months later; it continued to function in mid 2015. Data were telemetered to Earth throughout the mission from both its Space Environment Viability of Organics (SEVO) and Space Environment Survivability of Living Organisms (SESLO) payloads.

History

Development of the O/OREOS nanosatellite was initiated in August 2008 at the NASA Ames Research Center under the auspices of the NASA Astrobiology Small Payloads program as a demonstration mission. O/OREOS was successfully launched as a secondary payload on the US Air Force’s Space Test Program (STP) S26 Mission aboard a Minotaur IV rocket from Kodiak Island, Alaska, USA on November 19, 2010, to a 650-km, 72°-inclination circular orbit, with a period of 98 min. O/OREOS completed its primary 6-month mission successfully in May 2011. From November 2010 through August 2012, science data were telemetered to Earth from both of its experimental astrobiology payloads. Health-and-status data were also telemetered from the

spacecraft bus beginning in November 2010, continuing until the time of this writing (May 2015). On its outer surfaces, O/OREOS had received an estimated radiation exposure in excess of 15 kGy (15 kilogray) over the course of nearly 3 years in outer space; this is attenuated 100- to 1000-fold as a function of location within the satellite. Due in part to the additional drag provided by a novel “nanokite” deorbit mechanism, the O/OREOS nanosatellite is anticipated to re-enter Earth’s atmosphere and disintegrate in approximately 2032.

Overview

The O/OREOS experiments represent the first autonomous astrobiology and living biology studies conducted above the thermosphere in a cubesat/nanosatellite-class spacecraft.

The 1U SEVO payload incorporates a compact ultraviolet-visible-near-infrared (UV-vis-NIR) spectrometer, with the Sun as light source, and a 24-cell sample carousel housing four classes of vacuum-deposited organic thin film: ► [polycyclic aromatic hydrocarbon](#), ► [amino acid](#), metalloporphyrin, and quinone. These films are enclosed in hermetically sealed sample cells in one of four astrobiologically relevant microenvironments. The SEVO experiment spectroscopically monitored on a daily to biweekly basis the stability and changes in these organic films as they were exposed to solar far-UV, UV, visible, and near-infrared light (122–2600 nm), as well as trapped-particle and cosmic radiation (Mattioda et al. 2012). The SEVO payload successfully performed the first real-time in situ investigations of the photostability and dynamic changes of organic molecules and biomarkers in outer space, demonstrating a significant acceleration of photodegradation by photogenerated hydroxyl radicals in microenvironments that include water vapor. Spectral data sets from the 24 sample positions were typically downlinked within days of their acquisition, enabling rapid analysis and strategy modification of data collection parameters and timing in order to optimize science return.

The SESLO payload measured the long-term survival, germination, growth, and metabolic activity of *Bacillus subtilis* spores exposed for varying times to the microgravity, ionizing radiation, and heavy-ion bombardment environment (~1.7 Gy reached the cells over the course of 6 months). Multiple independent fluidic microwells containing wild-type (168) and radiation-sensitive mutant (WN1087) strains of dried *B. subtilis* spores were rehydrated with nutrients after 2 weeks, 3 months, and 6 months in orbit, causing the spores to germinate and grow. The growth medium included Alamar blue viability dye, which changes color as a result of cellular metabolism. Three-color transmitted intensity measurements of all microwells were telemetered to Earth for evaluation and interpretation (Nicholson et al. 2011) in comparison to delayed-synchronous laboratory ground control experiments. Data telemetered by SESLO showed that both *B. subtilis* strains of cells in microgravity generally grow and metabolize more slowly than those subjected to Earth’s gravitation.

OB Association

Steven W. Stahler

Department of Astronomy, University of California, Berkeley, CA, USA

Definition

An OB association is a loose grouping of several thousand stars, a small fraction of which are of spectral type O and B. These latter are the most massive members of the group and also the most luminous, allowing identification of OB associations out to great distances. In external spiral galaxies, they trace the spiral arms. OB associations range in size, with diameters from tens of parsecs to about 100 pc. It is thought that all the stars formed together in a tighter configuration, and observations of stellar velocities reveal that the groups are in a state of expansion. The oldest recognizable OB associations have ages of order 10 Ma.

Obduction

Nicholas Arndt

ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Obduction is the geological process which describes the thrusting of segments of ► [oceanic crust](#) and ► [mantle](#) onto ► [continental crust](#) at convergent plate margins. A slice of obducted oceanic crust is called an ophiolite. Commonly, high-pressure low-temperature metamorphic rocks belonging to the so-called blueschist-facies

are exposed in front of the obducted ► [ophiolite](#). During periods of enhanced ridge push, while most of the oceanic plate is subducted, slices of younger (and thus hotter and more buoyant) material are thrust onto small continental fragments or onto the margins of continents, particularly during the closure of ocean basins preceding continent-continent collision.

Oberon

Therese Encrenaz
Observatoire de Paris – Section de Meudon,
Meudon, France

Definition

Oberon, discovered by Herschel in 1787, is the outermost of the five big satellites of ► [Uranus](#). Its distance to Uranus is 583,500 km (or 23 Uranian radii), its diameter is 1520 km, and its density is 1.63 g/cm³. Oberon has been observed by the Voyager 2 spacecraft at the time of its ► [Uranus](#) flyby in January 1986. Its surface is heavily cratered; the largest crater, Hamlet, has a diameter of 206 km. It is considered as being differentiated into a silicate core surrounded by an icy mantle. The low albedo (0.14) of the surface suggests that it consists of a mixture of ice and organic matter, possibly irradiated by high-energy particles coming from Uranus’ magnetosphere.

Obliquity and Obliquity Variations

François Forget
Institut Pierre Simon Laplace, Laboratoire de
Météorologie Dynamique, UMR 8539, Université
Paris, Paris, France

Synonyms

[Axial tilt](#)

Definition

In astronomy, the obliquity is the angle between an object’s (e.g., planet’s) axis of rotation and a line perpendicular to its ► [orbit](#) plane. The obliquity controls the variation of insolation with latitude and time, and thus influences the climate.

Overview

In the Solar System, the present-day obliquities of the planets are diverse Table 1.

Planetary obliquities vary with time because of the long-term gravitational perturbation by other planets (Laskar and Robutel 1993). This effect is small on the obliquity of the outer planets (► [Jupiter](#), ► [Saturn](#), ► [Uranus](#) and ► [Neptune](#)), which can be considered as primordial: They have roughly kept the value they had at the end of the

Obliquity and Obliquity Variations, Table 1 Obliquity of the eight planets of the Solar System and Pluto

Planet	Obliquity
Mercury	0.01°
Venus	177.4°
Earth	23.45°
Mars	25.19°
Jupiter	3.1°
Saturn	26.7°
Uranus	97.8°
Neptune	28.3°
Pluto	122.5°

formation of the ► [Solar System](#). In contrast, the very low obliquity of ► [Mercury](#) results from tidal interactions with the Sun. This is also the case for ► [Venus](#), although the effect was different because of its thick atmosphere (the Sun heats the atmosphere at the subsolar point, inducing a redistribution of the mass of the atmosphere, which also induces a torque). For the ► [Earth](#), the obliquity presents only small variations of about 1.3° around the mean value of 23.3° , with a dominating period of 42,000 years. In the absence of the Moon, theoretical calculations suggest that the situation would be very different, as multiple resonances then occur between the precession of the axis and the precession of the orbital plane. Earth's obliquity would then have varied widely between nearly 0° and 85° . In fact, this is the case for Mars, which may have varied between $\sim 0^\circ$ and up to more than 60° . In the past 5 Ma, the Martian obliquity varied (with a pseudo-period near 120,000 Earth years) between about 15° and 35° . Between 5 and 20 Ma ago, it oscillated between $\sim 25^\circ$ and 45° . Before that, it is impossible to reconstruct the details of the obliquity variations, because of the chaotic nature of the problem (Laskar et al. 2004).

On any planet, the obliquity controls the distribution of solar illumination with latitude, and the seasonal cycle. Increasing the obliquity enhances the seasonal variations (warmer summer, colder winter). The average annual insolation slightly decreases with obliquity equator ward of 45° latitude, and strongly increases with obliquity pole ward of 45° latitude. At the poles, it is proportional to the sine of the obliquity.

Occultation

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

In astronomical usage, an occultation occurs when an object of larger angular size passes in front of an object of smaller angular size. A frequent example is the passage of the Moon between an observer on Earth and a star, producing an occultation of the star. The rarer occultations of stars by planets, satellites, or asteroids provide opportunities to probe the properties (atmosphere, size) of the occulting bodies. Such observations led to the discovery of the rings around the planets ► [Uranus](#) and ► [Neptune](#). When the Earth passes through the equatorial plane of ► [Jupiter](#) or ► [Saturn](#) (which correspond to the orbital planes of the major satellites of these planets), mutual occultations among these satellites can be observed. Occultation events have also been observed from unmanned space probes in the Jovian and Saturnian systems. The case when the foreground object has a smaller angular size than the more distant object is called a ► [transit](#).

Definition

Ocean planets are hypothetical objects with masses ranging from 2 to 10 Earth-masses and primarily

made of water. The surface of an ocean planet is assumed to be completely covered by an ocean with a depth that can reach hundreds of kilometers (Fig. 1). Because of the massive presence of liquid water on their surfaces, ocean planets may be good candidates for the detection of life if they are in the Habitable Zone. No ocean planet has yet been detected; however, some recently discovered planetary bodies such as Kepler 22b may present potential candidates for an ocean planet.

Oceanic Crust

Nicholas Arndt

ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Oceanic crust is the outer solid layer of the Earth beneath the oceans. This type of crust is 6–9 km thick, it is essentially basaltic (mafic) in composition and denser of the continental crust. It comprises three main layers (from top to bottom): Layer 1, a thin layer (typically less than 500 m thick) of deep-water unconsolidated carbonate or siliceous sediment that thin towards mid-ocean ridges; Layer 2A consisting of ~0.5 km thick, glassy-to-finely crystalline basalt, usually in the form of pillow lava; Layer 2B, consisting of ~1.5 km thick sheeted vertical diabase (a rock essentially basaltic in composition but slightly metamorphosed) dykes; and Layer 3, ~5 km thick and of a density of 3.0 g cm^{-3} consists of gabbro (the intrusive form of basalt) and ultramafic cumulates (peridotite). The crust forms through partial melting of upwelling mantle beneath mid-ocean ridges; the layering results from differentiation of the basaltic magma produced by this melting. On Earth, the age of oceanic crust ranges from zero at oceanic spreading centers to a maximum of about 180 Ma in the northwestern Pacific.

Definition

The chemical composition of the ocean corresponds to the composition of its major and minor dissolved ions (Na^+ , Mg^{2+} , Ca^{2+} , K^+ , Sr^{2+} , Cl^- , SO_4^{2-} , HCO_3^- , Br^- , CO_3^{2-} , B^{3+} , F^-). The major ion content is considered relatively constant and defined as salinity, which is a measure of the total dissolved salts in seawater. The chemical evolution of the terrestrial oceans is controlled by complex interactions between the Earth system reservoirs, namely the geosphere (mantle and crusts), the biosphere, the atmosphere, and the hydrosphere itself.

Overview

Ocean Chemistry: The Result of Complex Interactions in the Earth System

Table 1 resume the average chemical composition of the Earth's modern oceans with the concentrations of the main ions dissolved in the seawater (in mol/g) and corresponding to an average salinity of 35 g/L (or ca 35,000 ppm, being the density of water equal to 1.025 kg/L). Salinity in the

Oceans, Chemical Evolution of, Table 1 Standard mean seawater chemical composition (Salinity = 35 g/L) reported as mol kg H₂O⁻¹ (DOE 1994). Boron is reported as sum of its hydroxides B(OH)₃ and B(OH)₄

Ion	Na ⁺	Mg ²⁺	Ca ²⁺	K ⁺	Sr ²⁺	Cl ⁻	SO ₄ ²⁻	HCO ₃ ⁻	Br ⁻	CO ₃ ²⁻	B ^{3+,4+}	F ⁻
mol/g	481.6	54.75	106.5	105.8	0.09	565.67	29.27	1.83	0.87	0.27	0.43	0.07

present oceans is relatively constant, between 31 and 38 g/L, yet several processes can cause the oceanic waters to be nonconservative. These processes include precipitation, dissolution, water-rock interactions, freezing, and oxidation processes (Millero 2003). For example, dilution from abundant monsoon-related rain or ice debacle can locally and substantially reduce the salinity, while marginal basins with restricted circulation and tropical temperatures (i.e., the Dead Sea) can increase dramatically the salinity by evaporation.

The chemical composition of the oceans is the result of complex interactions between all the reservoirs of the Earth. If the salinity of the oceans could be basically reduced to two main sources, namely the mantle which degases ► [halogens](#) both at the ► [mid-ocean ridges](#) and at the volcanic arcs (e.g., Schilling et al. 1978) and the continents which release cations and anions by rock ► [weathering](#) (hydrolysis, dissolution, etc.), all other reservoirs have played a role in modulating these sources through eons. For example, a CO₂-rich atmosphere that lasted for most of the Precambrian and part of the Phanerozoic certainly contributed to accelerate continental weathering through the Urey reaction (silicate weathering by CO₂ with precipitation of carbonates; Urey 1952), rendering the continents the main source of alkalinity eventually stored as carbonates (Albarede et al. 2020). On the other hand, the record of strontium isotopes (⁸⁷Sr/⁸⁶Sr) in Archean marine carbonates show values of 0.703–0.704 very close to those of the upper mantle (Veizer and Compston 1976) and far from the present-day ocean of 0.709, which reflect the dominant source of Sr and other elements from continental weathering (the ⁸⁷Sr/⁸⁶Sr ratio of the riverine input is 0.711). Following mass and isotopic balance calculations these numbers suggest that only 20% of the continental mass lands were present in

the Archean period. Similar numbers are obtained by Albarede et al. (2020) looking at the phosphorous contents in marine mudstone of different ages from Archean to the present-day. The only significant input of phosphorus in the ocean is continental runoff. Phosphorus concentration in mudstones expresses the ratio between chemical and mechanical erosion. As such, the phosphorus abundance in mudstones can be used to infer continental surface area. Based on compiled data and the progressive increase of phosphorous abundance in mudstone since earlier Archean, Albarede et al. (2020) suggest that at the time of the oxygenation of the earth (2.5 Ga ago), the continents were covering 7% of the Earth's surface against 30% of the present-day continental landmasses, making the Earth resembling an ► [Ocean-Planet](#) or aquaplanet.

Earlier little developed biosphere and smaller continental landmasses could have modulated the content of some halogen such as I and Br, which in modern ocean is uptake by plankton and removed from the ocean by burial of organic matter in sediments (Channer et al. 1997). Appearance and domination of C-fixation probably had a key role in producing and accumulating O₂ in the atmosphere and removing iron from Archean ferruginous oceans as ► [banded iron formation](#) (Catling 2015), while the absence of some metabolic pathway in earlier times, as sulfate-sulfide reaction could have contributed to maintain a low-sulfate ocean in the Archean (e.g., Crowe et al. 2014). More simply, the lack of oxygen in the pre-GOE atmosphere, SO₄²⁻ and NO₃⁻, which dominate the redox chemistry of modern seawater, were essentially absent in the Archean Ocean, while iron was overwhelmingly in its Fe²⁺ form (Albarede et al. 2020).

Tectonic processes shaping the geosphere have also a key role in ocean chemistry. There is a general accepted idea that Hadean and Archean

Ocean' salinity – prior of the onset of the modern plate tectonic somewhere around 3.0 Ga ago – was dominated by ions derived from mantle degassing (halogens, metals...) and from weathering of oceanic basaltic crust by intense hydrothermal fluid circulation (Pinti 2005). This would be a direct consequence of a much vigorous mantle convection favoring higher oceanic crust production at mid-ocean ridges (Bickle 1986) and the limited growth of continents (McCulloch and Bennett 1994). With the beginning of the plate tectonic and an effective way of recycling elements down the mantle through subduction, both halogens and other elements may have been constantly cycled between the surface and the interior of the Earth (Schilling et al. 1978) modifying the chemistry of seawater. Further, the rapid growth of continents should have progressively favored weathering and riverine transport of new elements to seawater. Continental landmass growth might have also locked important mass of salts in continental evaporitic settings decreasing at least of a factor 1.2 to $2\times$ the halite (NaCl) content of the primordial oceans (Knauth 2005). Several authors indicate the beginning of the Proterozoic era as the turning point in the dominance of salinity sources (hydrothermal cycling versus continental weathering; Veizer et al. 1989; de Ronde et al. 1997; Pinti 2005). There are also physical parameters to consider and which plays a role in the distribution of solute in the oceans. Presently on Earth the latitudinal distribution and the extent of continental landmasses control the global oceanic circulation and the formation of deep waters in what is known as the thermohaline circulation or the ocean conveyor belt (Broecker 1991). In an aquaplanet, oceanic circulation as known today is disrupted and the upwelling of cold current is stopped. This situation certainly plays a role in the redistribution of solutes in the ocean.

It is clear from these few, first order thoughts that modeling the evolution of the seawater chemistry is a hard task, because the multitude of physical, chemical, and biological variables that enter the general equation of the ocean chemistry. Yet, the geological record has left traces of the past chemistries of the oceans, some easy to be read and correctly interpreted, other ambiguous

because hampered by alteration and metamorphism. These include rare earth elements (REE) in chemical sediments precipitated in the oceans or isotopic signatures of biophile elements C, S, N (Thomazo et al. 2009) in these sediments. Here, below we report a general review of the knowledge around the early ocean chemistry evolution restricted to Hadean and Archean times, which is far to be exhaustive. Even after 37 years, the general work of Holland (1984) is still actual and to be read for understanding the numerous Earth system processes that could or have intervened in creating and modifying the oceanic chemistry through eons. Very recently Albarede and colleagues (Albarede et al. 2020) have dig potential processes affecting the Archean Ocean, presenting a fresher view of the element cycling in the oceans.

Halite: The Main Ingredient of Seawater' Salinity

Present-day ocean salinity is at 71% in mass (g/g) made of only two ions, namely sodium (Na^+) and chloride (Cl^-) which precipitation makes the most abundant evaporite mineral, halite (NaCl). This chemistry might have been dominant since the beginning. Chlorine is the most abundant halogen on Earth, followed by far by bromine, which is at least 3 orders of magnitude less abundant (Eggenkamp 2014). In the cosmochemical classification of the elements, halogens are volatile elements, as ► noble gases are, but differently from noble gases, they are highly reactive elements, displaying a preference for aqueous phases (Eggenkamp 2014; Clay et al. 2017). Therefore, they are mainly concentrated in the oceans ($\text{Cl} = 19,353$ ppm and $\text{Br} = 67$ ppm) and evaporites ($\text{Cl} = 607,000$ ppm and $\text{Br} = 151$ ppm) (Eggenkamp 2014). They were delivered to Earth, as other volatile elements (noble gases, N, C, H_2O), very early in the history of the Solar system during the first stage of the Earth' accretion (Clay et al. 2017). This is suggested by the close similarities in the Cl/Br ratio of chondrites and major Earth reservoirs (Clay et al. 2017) and the very close isotopic signature of chlorine ($\delta^{37}\text{Cl}$ in ‰ vs Standard Mean Oceanic Chloride or SMOC) in seawater (0‰ by definition),

chondrites ($+0.2 \pm 0.5\%$; Sharp et al. 2007) and the mantle (-1.6 to $+0.9\%$; e.g., Bonifacie et al. 2008; Pinti et al. 2020). Halogens were incorporated in the Earth and then degassed from the mantle, which is today mostly entirely depleted in halogens. However, halogens have not undergone the extreme early loss observed for other mantle volatiles, such as noble gases. The hydrophilic nature of halogens could have played a role in preserving them in surface aqueous phases, less affected by devolatilization processes during early accretionary events (Clay et al. 2017).

If chlorine and other halogens were present on Earth very early, sodium – the other element composing halite – was likely abundant on early Earth, locked in mineral phases such as plagioclases in the basaltic oceanic crust. Hadean ocean salinity was possibly controlled by high-temperature water-rock interactions between the condensing CO_2 – H_2O runaway greenhouse atmosphere and the primitive basaltic crust (Sleep et al. 2001). When condensing water started to penetrate deeper in the oceanic basaltic crust, dissolved chlorine (degassed from the mantle likely as HCl) reacted with Na-bearing minerals of basalt to produce halite (NaCl). Sleep et al. (2001) calculated that a global basaltic layer only 500-m thick could have accounted for the whole ocean NaCl budget. Initial salinity of the ocean is unknown, and values of 1.2–2 times the present value have been proposed only for the Archean ocean (Knauth 2005). This could be considered a minimum value for the Hadean.

The presence of halite in early oceans has been contested by some authors (i.e., Maisonneuve 1982) because it was believed that chlorine was sourced by weathering of continental evaporitic deposits. However, it is likely that the total budget of chlorine was available in oceans since the beginning, largely degassed from the mantle (Clay et al. 2017). An alternative model to a salty early ocean was proposed by Kempe and Degens (1985) which evoked the possibly to have an alkaline soda ocean, an environment similar to that observed in modern ► [soda lakes](#). The presence of high $p\text{CO}_2$ in the early atmosphere, 100–1000 times the present concentration, should

have brought to the acidification of the oceans but increased the amount of Ca^{2+} and bicarbonate in solution through silicate weathering. This in turn should have decreased the amount of $p\text{CO}_2$ with time, consumed by the Urey reaction. Although counterintuitive, in presence of relatively high $p\text{CO}_2$, hydration of Na–, K–, Ca–, and Mg-silicates produces alkaline solutions, which brought to precipitation of sodium carbonates (Na_2CO_3) (Kempe and Degens 1985). However, thermodynamic calculations indicated that the whole terrestrial available CO_2 budget (atmosphere-hydrosphere-mantle) is several orders of magnitude lower than the one needed to make a global soda ocean (Sleep et al. 2001).

If NaCl was since the beginning dominant in the early oceans, the total amount is still matter of speculation, but estimating it has important consequences on the early existence of a marine biosphere. Holland (1984) calculated an early NaCl salinity $1.2\times$ the present day, while Knauth (2005) taking into account all large evaporitic deposits on continental landmasses reaches a higher figure of $2\times$ the present-day amount. An ocean this saline would be a problem for most metazoans today, but its effect on prokaryote is not significant. Cyanobacteria, for example, have little problem with this enhanced salinity and extremophiles (Archaea halophiles) are known to live in highly concentrated brines with salinities ranging from 4.7% to 30% (against 3.5% of modern seawater).

There are other suggestions that chlorinity was higher in the pre-GOE seawater based on seawater chemistry (Albarede et al. 2020). In present-day seawater alkalinity of the ocean is locked into carbonates. With smaller landmasses affected by weathering, the main source of carbonates and mudstone was drastically reduced and consequently the flux of alkalinity to the ocean was much weaker than today. The control of seawater alkalinity, which today is exerted by the Ca^{2+} – CaCO_3 couple, was likely exerted by dissolved Fe^{2+} –magnetite or Fe^{2+} –ferrihydrite which buffered the atmosphere by reducing CO_2 to CH_4 and thus exerting an indirect control on the alkalinity of the ocean (Thibon et al. 2019). The

reduced alkalinity flux implicitly reduces the capacity of runoff to neutralize the high-temperature acidic hydrothermal fluids, with causes lower seawater pH and higher chlorinity.

Fluid Inclusions in Chemical Sediments and Ocean Chemistry

Direct measurements of past salinity have been tempted by analyzing fluid inclusions in chemical sediments of Archean age, amid the pristine nature of those inclusions (Appel et al. 2001; Foriel et al. 2004; de Ronde et al. 1997; Weiershauser and Spooner 2005; Marty et al. 2018; Burgess et al. 2020). The 3.8 Ga Isua meta-sedimentary sequences of West Greenland contain chemical sediments deposited in an oceanic environment without a significant silicic (i.e., composed of rocks rich in silica and alumina) detrital component (Holland 2003), in other words without continental inputs of ionic species. Compelling evidence for the existence of an ocean during deposition of Isua rocks are clastics that have been interpreted as marine turbidites and iron formations (IFs). These iron-rich layers are magnetite-quartz IFs, and the molar ratio $\text{Fe}_2\text{O}_3/\text{FeO}$ is less than 1.0, which suggests that [magnetite](#) was the dominant iron oxide and that [hematite](#) was absent or very minor in these IFs (Holland 2003). This in turn suggests that magnetite is not a replacement of oxyhydroxide precursors but a primary precipitating phase, thus that the oxygen level in the oceans was significantly low. The oxidation of Fe^{2+} to Fe^{3+} was possibly produced by UV-induced reactions between iron and H_2O (Cairns-Smith 1978). The chemistry of Isua seawater is unknown. Appel et al. (2001) observed fluid inclusions in quartz globules from pillow breccia at Isua. The chemistry of the highly saline aqueous fluids (about 25 wt.% NaCl equivalent) bears a strong resemblance to present-day seafloor hydrothermal fluids that likely provoked the alteration of the pillow breccia and the precipitation of quartz. Occurrence of fluid inclusions in Archean metasedimentary rocks (see [Fluid Inclusions](#)) has been signaled in several terrains of ages spanning from 3.5 to 2.7 Ga (De Ronde et al. 1997; Channer et al. 1997; Foriel et al. 2004;

Weiershauser and Spooner 2005). They have been interpreted as a pristine record of the chemical composition of Archean seawater. The chemistry of these inclusions pointed out to the mixing between at least two fluids, a saline fluid of Na–Ca–Cl composition (seawater) and a hydrothermal effluent often richer in Ba and Fe (de Ronde et al. 1997; Foriel et al. 2004). The Na:Cl ratio is the same as present-day seawater, but NaCl concentration ranges from 4% to 25% equivalent (against 3.5% equivalent in modern seawater). The salt enrichment and the chemistry (Na–Ca–Cl) points out to an evaporate seawater residue rather than genuine seawater (Martin et al. 2006). Marty et al. (2018) pointed out that the Archean inclusions contain fluids which are a mixture of a low salinity endmember, regarded as the Archean oceanic water, and several hydrothermal end-members rich in Cl, K, N, and radiogenic parentless ^{40}Ar . They concluded that the salinity of the Archean seawater endmember is basically the same than modern ocean. Among the notable differences with modern seawater, Burgess et al. (2020) measured Br/Cl ratios about 30% higher than both modern seawater and contemporary seafloor hydrothermal systems, perhaps indicating a stronger mantle buffering of seawater halogens during the Archean.

Basic Methodology

The complexity of the task of reconstructing the ocean chemistry through eons require to use numerous methods, from detecting and interpreting traces of the ocean lefts in the geological record to geochemical modelling. The first methodology required to find either pristine fluid inclusions in early chemical sediments precipitated directly from oceanic aqueous solutions and to measure [Rare Earth Elements](#) (REE) geochemistry and rock mineralogy of those mineral precipitates. This method faces two serious problems: (1) find appropriate rocks of Archean time having preserved original features and not heavily metamorphosed and (2) chemical marine sediments directly precipitated into oceans, when

the majority of the Archean geological record is made of magmatic and metamorphosed rocks. Indeed a few sedimentary sequences are older than 3.0 Ga and often marine sediments are overprinted by hydrothermal silicification which bring into elements from mantle-derived environments which partially masked those from the Earth's surface reservoirs. Often these sediments are simply chert deposits, which origin is still debated: either hydrothermal silica gel deposits around vents (analogue of modern white smokers; e.g., Orberger et al. 2006) or directly precipitated from an Archean ocean oversaturated of silica (Holland 1984; Knauth 2005). The analysis of REE generally allow to determine the sources of sediments and the real influence of the ocean on the sediment deposition, helping in unravel chemical-physical properties (pH, redox) of the seawater. Isotopes of biophile elements such as C, N, S and bio-mediated metals (Fe) were also helpful because their isotopic fractionation is related to some redox conditions of the oceans (e.g., Thomazo et al. 2009 for a review).

Key Research Findings

1. Although resulting from complex interactions among all the Earth's reservoirs, the ocean's chemistry is mainly regulated by two sources: (1) the mantle, through degassing of halogens and metals (Fe, Mn, etc.) at mid ocean ridge and release of ions (e.g., Na^+ , Mg^{2+} , Ca^{2+} , Sr^{2+}) during hydrothermal alteration of oceanic basaltic and gabbroic crust (e.g., Staudigel 2003); (2) silicate weathering of continental landmasses with riverine transport to the sea of ions removed from rocks.
2. Salinity of oceans has been likely always dominated by NaCl, with chlorine brought on Earth during waning stages of accretion and likely before the Moon-forming impact, and sodium extracted by basaltic protocrust.
3. Pristine Archean fluid inclusions indicate a Na/Cl ratio constant and similar to modern seawater, though chlorine concentration in the Archean Ocean is still matter of debate.

Applications

A complete picture of the seawater geological history on Earth could be extremely useful in determining the existence of past oceans on other telluric planets such as Mars, through the study of "sedimentary" rocks and chemical precipitates of "marine" origin.

Future Directions

The geological record of the seawater is still much incomplete and spotty. Bringing new evidence that pristine seawater fluid inclusions could have been preserved through eons and finding fluid inclusions containing nonevaporated seawater are the most challenging research to carry out in the next decade to clearly assess the chemical evolution of the oceans.

Definition

The term “ocean” applies to the entire body of saltwater covering more than 70% of the Earth's

surface. From a planetary point of view, the term can be extended to the layer of liquid that partially or totally covers the surface or pervades the sub-surface of a planet or a moon. Examples of sub-surface oceans are those predicted beneath the icy surface of satellites orbiting giant planets (e.g., Titan, Europa, and Enceladus). In addition to water, the term includes other substances such as ethane, methane, or ammonia that are in a liquid state at the temperature and pressure conditions of the planetary surface. The liquid body at the planetary surface can be in thermodynamic equilibrium with an atmosphere or may be separated from it by another layer such as solid water ice.

Overview

This overview focuses on the formation of the Earth's oceans. There are geological evidences that the oceans were present on the ► [Earth](#) in the early Archean (3.8 Ga ago) after the ► [Late Heavy Bombardment](#) and plausible evidence that liquid water was stable on the Earth's surface in the ► [Hadean](#) (Mojzsis et al. 2001; Wilde et al. 2001). The geological evidence comes from the two oldest areas of volcanic and sedimentary rocks – the Isua Supracrustal Belt, West Greenland, and the Nuvvuagittuq Greenstone Belt, Québec, Canada. Radiometric dating of metasedimentary rocks in both areas have been established at about 3.8–3.7 Ga (Cates and Mojzsis 2007; Augland and David 2015; Bennett and Nutman 2013). In the Isua Supracrustal Belt, pillow basalts provide evidence of subaqueous eruption, and in both belts, metasedimentary rocks – ► [banded iron formations](#), metapelite, and ferruginous quartzite – are possibly the result of subaqueous deposition. Although the original depositional setting of some of the precursor sediments may have been lakes or shallow seas, it is far more probable that these strata were deposited in ocean basins.

The evidence for Hadean oceans is less direct, because the geological record has been mostly erased by the intense tectonic activity of the young Earth. Most evidence comes from 4.4 to 4.2 Ga-old detrital zircons (ZrSiO_4) from the Mt. Narryer quartzite and from Jack Hills

metaconglomerate, Western Australia (Mojzsis et al. 2001; Wilde et al. 2001). ► **Zircon** is a common U-rich trace mineral in felsic magmas formed by the melting of a hydrous source. Parental rocks of the Jack Hills zircons possibly formed from melting of subducted hydrated oceanic crust. The presence of such a crust requires interaction between basaltic lava and seawater as is suggested by the $^{18}\text{O}/^{16}\text{O}$ ratio (denoted as $\delta^{18}\text{O}$) of the Jack Hills zircons which extend to $+7.4 \pm 0.7\%$. This value can be explained only by mixing between the mantle source of the zircons ($\delta^{18}\text{O}_{\text{Oca.}} +5.0\%$; Valley 2003) and a source enriched in ^{18}O compared to the mantle value, derived from low-temperature ► **weathering** of oceanic crust. The $\delta^{18}\text{O}$ values of Hadean, Archaean, and Proterozoic zircons show a secular increase in values up to 12%. This can be explained by an increase in the amount of crustal, high- $\delta^{18}\text{O}$ material available for melting and assimilation, as the “wet” continental crust evolved and matured during the Precambrian. The presence of $\delta^{18}\text{O}$ of $+7.4 \pm 0.7\%$ in a 4.4 Ga-old detrital zircon of Jack Hills could thus be the indirect and oldest record of interaction of a magmatic source with liquid water at the surface of the Earth (Peck et al. 2001; Valley et al. 2005). A similar result was obtained by measuring the lithium (Li) isotopic ratio ($^7\text{Li}/^6\text{Li}$ or $\delta^7\text{Li}$) in Jack Hills zircons (Bouvier et al. 2012). Fresh igneous rocks have $\delta^7\text{Li}$ of $3.8 \pm 1.5\%$, whereas seawater has very high $\delta^7\text{Li}$ of $+31\%$. Fluid–rock interaction causes fractionation of Li with products of subaerial weathering as low as -20% . Two $\delta^7\text{Li}$ populations of zircons were identified by Bouvier et al. (2012). The first showed $\delta^7\text{Li}$ values similar to TTG and sanukitoids indicating growth from a differentiated magma source. A subset of Jack Hills zircons has extremely low $\delta^7\text{Li}$ (-18 to -4%), reflecting melting of extensively weathered crust.

The combination of geological observations together with geochemical and isotopic analyses –contributing in determining the climate and surface conditions of the Hadean Earth – led to the ► **“Cool Early Earth”** hypothesis according to which temperatures were clement, and oceans existed on the surface of the Earth as early as 4.4 Ga (Valley et al. 2002).

The source of the oceanic water is debated. It is commonly accepted that any primitive solar-type atmosphere surrounding the Earth was rapidly blown away by UV and X-rays produced by the Sun during its proto-(T-Tauri)-star stage. It is assumed that the Earth probably did not contain water, because it accreted very close to the Sun and largely composed of “dry” raw material, possibly enstatite chondrite (EC) ► **meteorites** (Javoy 1997). Previous measurements of water in EC indicated amounts close to 0.01 wt%, but in a very recent study (Piani et al. 2020), the amount and isotopic composition of water were measured again. It resulted that H_2O content could be as high as 0.5 wt% and the D/H (or δD) ratio ranges between -103 and -127% , less than that of the terrestrial oceans but within that of the Bulk Silicate Earth (-130 to -75%), Suggesting that EC could have participated to the ocean formation. Thus EC could be a complementary carrier of water to Earth, a hypothesis that needs to be further explored.

The present hydrosphere was probably acquired from meteoritic and cometary material that was added during repeated episodes of bombardment, which have been historically regrouped in the concept of “Late Veneer” (e.g., Wänke and Gold 1981). Late Vener is a term defined by geochemists to explain the observed abundance patterns of siderophile (iron-loving) elements in the silicate Earth. In particular, the elements of the group of Platinum (Pt) called HSE (High Siderophile Elements: Re, Os, Ir, Ru, Pt, Rh, Pd, Au) are anomalously enriched in the mantle, while after Earth differentiation, these iron-loving elements have been sequestered entirely into the metallic core of the Earth. This excess is explained by the late addition of chondritic material, which is known to contain high concentrations of HSE. It is still unclear how the “Late Veneer” precisely “fits” in the currently accepted, complex scenario of Earth’s accretion, involving both planetesimal bombardment and giant impacts from chondritic and differentiated projectiles (Morbidelli and Wood 2015). This issue is complicated by the fact that modern core-formation theories suggest that differentiation occurred in several steps, and consequently, several episodes of “Late Venner” could have taken place. Moreover, Earth

formation modeler's recently introduced the new concept of "Late accretion," which corresponds to the tail of the accretion history of a planet due to the planetesimal bombardment that happens after the last giant impact has occurred (the Moon-forming one in case of Earth, Morbidelli and Wood 2015). Here, it is assumed — in accordance with recent Earth's formation models that water was added very early in the accretion history of the planet (Morbidelli et al. 2000), and that this episode is distinguished from those of Late Veneer, which likely took place afterward.

The main question, which currently constitutes a hot debate among the scientific community, is the type of the impactor, which brought the main body of water to form these terrestrial oceans. Similarities between the hydrogen isotopic ratio D/H of the whole Earth ($149\text{--}153 \times 10^{-6}$), ocean water (155.7×10^{-6}), and the average D/H ratios of hydrated ► carbonaceous chondrites ($149 \pm 6 \times 10^{-6}$), and Antarctic micrometeorites ($154 \pm 16 \times 10^{-6}$) indicates that ► asteroids or asteroidal dust constitute the most likely water-carrier candidates (Maurette et al. 2000; Marty and Yokochi 2006). ► Comets apparently exhibit heavier D/H ratios of $290\text{--}320 \times 10^{-6}$ (as measured in Oort Cloud's long-period comets ► Hyakutake, ► Hale-Bopp, and P/► Halley) that are incompatible with oceanic water. However, mass and isotopic balance calculations suggested that eventually a few percent of cometary water contributed to the terrestrial water budget. The sustainers of the "cometary" origin of the Earth's water disagree with these results because the exact D/H signature of water in comets from the Oort Cloud is still unknown. Moreover, when the Solar System formed another family of comets, the Jupiter family formed in the region of the ► Kuiper belt, and those comets may have delivered ocean-like water to the inner Solar System. This is still controversial. Indeed, recent measurements of the D/H ratio in the Jupiter family comet 103P/► Hartley 2 by infrared spectrometry (Hartogh et al. 2011) showed a D/H ratio of $161 \pm 24 \times 10^{-6}$ supporting the view that this family of comets brought water to Earth. However, the ► 67P/Churyumov–Gerasimenko comet, supposed to have a similar origin to 103P/► Hartley 2,

yielded a $D/H = 530 \times 10^{-6}$, a value not compatible with the hypothesis of water delivery from this type of comets (Altwegg et al. 2015). Future measurements on carbon and water-rich asteroidal bodies, such as type-b asteroid Bennu targeted by NASA mission OSIRIS-REx, may definitely answer those questions.

The total amount of water delivered to Earth was certainly higher than the mass of the present-day oceans (1.4×10^{21} kg) because the losses of volatiles to space were important on the Early Earth. Pepin (1991) proposed that at least 50% of the water delivered to Earth could have dissociated to hydrogen and oxygen by the strong early UV radiation. Further losses were due to atmosphere erosion by impacts owing to collision with planetary bodies. Geophysical and high-pressure mineralogy experiments show that the modern mantle contains two to five times the ocean volume of water (Abe et al. 2000). Earth volatile bulk concentration (noble gases, halogens, and water) indicates that an addition of no more than 4% of carbonaceous chondrite "wet" material is enough to furnish the present-day volatile budget of our planet (Albarede et al. 2013). This amount of extra-chondritic material added the equivalent of 10–25 times the present-day ocean budget to Earth. Regardless of whether these figures will change with new studies, it appears that the amount of water added to the newly born Earth was much higher than that is preserved in the oceans.

Theories of how the ocean formed and stabilized on the surface of the Earth are based on geophysical models and speculation. Water, together with CO₂ (now trapped at the Earth's surface as carbonates), was initially a vapor phase in the secondary (outgassed) atmosphere. Water gas did not condense until the surface of the planet cooled down to less than 647 K, the critical point of water. Assuming that all oceanic water was present as a gas, the atmospheric pressure was about 270 bars of H₂O plus 40–60 bars of CO₂ (Sleep et al. 2001; Pinti 2005). This runaway greenhouse atmosphere, refurbished by a high heat flow from the still molten and highly dynamic interior of the Earth, kept the planet's surface sufficiently hot for several million years to prevent

water from condensing on its surface. When a primordial crust formed, it reduced the heat flux from the interior, and the surface of the Earth cooled down, allowing the condensation of water. It is difficult to assess exactly when this occurred. Geophysical models developed by Sleep et al. (2001) suggest that the oceans rained out a few million years or less after the Moon-forming impact, depending on the parameters chosen. If the geochemistry of the Jack Hills zircons does indeed reveal the presence of liquid water at the surface, oceans should already present between 4.4 and 4.3 Ga or, at least, liquid water was stable at the surface conditions of Earth. In such a scenario, the oceans cooled down quickly enough to render both prebiotic chemistry and the survival of the first living organisms possible between ~4.3 Ga and the end of the late heavy bombardment at ~3.85 Ga.

The chemistry of seawater in the early Hadean was likely controlled by high-temperature fluid-rock reactions between the hot CO₂-H₂O-rich atmosphere and oceans, and primitive basaltic crust (see ► “Oceans, Chemical Evolution of”). Weathering of Na-rich basalt reacting with chlorine saturated the seawater with NaCl. The acidity of water was possibly as high as pH = 5 because the ocean was in thermodynamic equilibrium with a CO₂-rich atmosphere (Pinti 2005), though alternative models of alkaline oceans saturated with ► *thermonatrite* formed by weathering of the basaltic proto-crust have been proposed (Kempé and Degens 1985).

Basic Methodology

The origin of oceans is a long-standing question, both geological, and before that, philosophical, since Ancient Greece. American geologist William W. Rubey wrote in 1951, a seminal paper entitled “Geological History of Seawater. An attempt to state the problem,” in which he tried to resolve the origin of the atmosphere and the oceans, based on geological observations and mass balance calculations. This first “modern” attempt was based on the hypothesis of an internal

source: gases and water accumulated during accretion from colliding planetesimals, then degassed from the mantle via the volcanism, or released from rocks by surface weathering, formed the secondary atmosphere of our planet and the oceans. Only with the development of isotope cosmochemistry and the theory of the “Late Veneer,” that is, an episode of bombardment of asteroidal and cometary matter to the accreting Earth, an external origin of water “theory took place.” Since then, the main methodology is to compare the isotopic signature of water in terrestrial oceans and the bulk silicate Earth with those measured in other celestial bodies, from lunar rocks (e.g., Greenwood et al. 2011) to meteorites and comets (see below). The development of *in situ* measurements on small celestial objects (e.g., Rosetta mission) or sample return missions (Hayabusa 1 and 2 and OSIRIS-REx) now gives the chance to measure the isotopic signature of water on potential extraterrestrial candidates, as possible water carriers to Earth. Parallel to this, field geologists and geochemists on Earth seek traces of ancient water trapped in the oldest minerals and rocks to determine a minimum age of existence of water in the geological record (e.g., Wilde et al. 2001).

Key Research Findings

To help understand the origin of the oceans requires the integration of information from the Earth, where the ocean still exists and where a fragmentary record of its early state is preserved in the geological record, with information from other planetary bodies. Studies of the Martian surface have already provided evidence of the small shallow oceans that existed there early in the planet’s history; also, the cold icy satellites provide a record of very different oceans. This information can potentially be exported to models for the formation of oceans on exoplanets. Léger et al. (2004), for example, have proposed the existence of a hypothetical family of ► “ocean planets” that are entirely covered by an ocean hundreds of kilometers deep.

Future Directions

Two main questions need to be addressed: (1) When did oceans form on Earth? (2) What is the ultimate source of the water? The first question is difficult to answer because the answers must be sought from a period from which virtually no geological record exists. Two decades ago, this task seemed hopeless, but the remarkable results emerging from the Jack Hills zircons and other relicts of the oldest crust have radically changed our knowledge of this period. The search for and precisely date and analyze other minerals or rocks may provide complementary evidence of interaction with liquid water. To answer the second question, it is imperative on one side to remeasure at high precision, with new instrumentation such as ion microprobe, the collections of different meteorite classes to correctly establish the amount of hydrate minerals and water isotopic signature; from the other side, analyses of pristine material brought back by recent space missions on asteroids, such as Hayabusa 2 and OSIRIS-Rex, should be able to establish to what extent and which asteroidal material could have contributed to the terrestrial water budget.

Oceanus, Oceani

Stephan van Gasselt
Planetary Sciences and Remote Sensing, Institute of Geological Sciences, Freie Universität Berlin, Berlin, Germany

Definition

The term Oceanus refers to a large low-albedo feature – Oceanus Procellarum – on the Moon. Oceanus Procellarum (ocean of storms) is the only surface feature to which the term Oceanus is applied. It denotes the largest Mare area on the Moon. Oceanus Procellarum extends approximately 2500 km across and covers a surface area of 4 Mio. km². It is composed of extensive flood basalts but is not confined to an isolated impact crater or basin as it connects several Mare-type features. Oceanus Procellarum was sampled during the Luna and Surveyor missions and was visited by the Apollo 12 astronauts in late 1969.

Odin

Ake Hjalmarson

Chalmers University of Technology, Gothenburg,
Sweden

Definition

Odin is a Swedish-led submillimeter wave spectroscopy satellite for astronomy and atmospheric research, supported by scientists and space agencies in Canada, Finland, France, and Sweden (>51%). The satellite is equipped with a 1.1 m antenna, four tunable submillimeter wave mixer receivers, a fixed-tuned receiver at 119 GHz dedicated to deep searches for molecular oxygen, O₂, and an optical/near-infrared receiver for aeronomy purposes. Odin was launched from far eastern Russia on 20 February 2001 and still is in full operation in 2013. The central aeronomy program consists of global, long-term temporal monitoring of the distributions of ozone and connected species such as ClO. The astronomy program was mainly dedicated to observations H₂O, NH₃, and O₂ in comets, planetary atmospheres, star formation regions, and circumstellar envelopes around late-type stars. For the last years the mission is focusing on atmospheric research. Odin and NASA's SWAS (launched 2 years earlier) have both provided important pilot studies for the larger and much more sensitive Herschel Space Observatory.

Definition

OGLE-2005-BLG-390Lb is a cool ► [super-Earth](#) that was discovered with the gravitational microlensing technique by the Probing Lensing Anomalies NETwork/Robotic Telescope Network (PLANET/Robonet), ► [Optical Gravitational Lensing Experiment](#) (OGLE), and ► [Microlensing Observations in Astrophysics](#) (MOA) collaborations. The mass and orbital separation of the planet are uncertain, as is the mass and distance of the host star from the Sun, but the most likely values are a mass of ~5.5 Earth masses and projected separation of 2.6 AU for the planet and a mass of 0.22 solar masses and a distance of 6.6 kpc for the host star. With an equilibrium temperature of ~50 K, this low-mass planet is located in the cool, outer reaches of its planetary system; it is the first such planet discovered by any technique. Studies by Ehrenreich et al. (2006) suggest that the surface of the planet should be entirely frozen. However, depending on the rock-

Oligomer

Gözen Ertem

National Institutes of Health, Bethesda, MD, USA

Definition

The term oligomer is derived from the Greek “oligos,” meaning “a few.” In chemistry, an

oligomer is a short polymer consisting of approximately five monomer units, although agreement as to the strict length cutoff is debated and varies between four and one hundred. Oligomers are formed by oligomerization, which involves linking the monomer units together in a chemical reaction. Unlike a ► [polymer](#), if one of the repeating units of oligomer is removed, its chemical properties may be significantly altered.

In biochemistry, the term oligomer is commonly used for short, single-stranded DNA fragments, used in ► [hybridization](#) experiments as ► [primers](#). It can also indicate a short protein made of two or more subunits.

Oligomerization

Shin Miyakawa

6-1-7 Minami Hatsutomi, Kamagaya, Chiba,
Japan

Definition

Oligomerization is a chemical process that links monomeric compounds (e.g., amino acids, nucleotides, or monosaccharides) to form dimers, trimers, tetramers, or longer chain molecules (oligomers). Examples are the conversion of nucleotides to oligonucleotides and amino acids to peptides. The boundary between what is considered an oligomer and a ► [polymer](#) is unclear, but it is usually accepted to be in the range of 10–100 monomer units. Prebiotic experiments have shown that ► [activated nucleotides](#) can be oligomerized using ► [clay](#) minerals as catalyst.

Oligonucleotide

Kunio Kawamura

Department of Human Environmental Studies,
Hiroshima Shudo University, Hiroshima, Japan

Keywords

Chemical evolution · Nucleotide ·
Oligonucleotide · RNA

Synonyms

[DNA](#); [Nucleotide oligomer](#); [RNA](#)

Definition

An oligonucleotide is a relatively short RNA or DNA polymer linked via phosphodiester bonds. Under prebiotic conditions, oligonucleotides of RNA can be formed from ▶ [activated nucleotide](#) monomers including different kinds of nucleotide bases: ▶ [guanine](#), ▶ [adenine](#), uracil, ▶ [cytosine](#), and ▶ [hypoxanthine](#). The oligonucleotides of RNA formed under the primitive earth conditions normally contain both 2', 5'- or 3', 5'- linkages and often contain a 5'-residue linked by a diphosphate linkage.

Overview

The formation of oligonucleotides would have been an essential step for the emergence of life on the

primitive earth. In modern organisms, polymerization of RNA or DNA monomers merely proceeds from nucleoside 5'-triphosphate monomers in the presence of DNA template and specific enzymes. On the contrary, the prebiotic formation of RNA with 50 nucleotide units in length proceeds from nucleoside 5'-phosphorimidazolides under simulated primitive earth conditions. However, the prebiotic formation of DNA does not proceed from such activated nucleotide monomers.

Although the usage of condensation reagents is possible to form oligonucleotides from nucleotide monomers, the activated nucleotides are more effectively used to form long oligonucleotides with high yield. Continuous investigations have been carried out to identify the pathways for prebiotic formation of RNA oligonucleotide. Successful examples include the oligonucleotide formation from the activated nucleotide monomers in the presence of metal ions (Sawai [1976](#)), that in the presence of montmorillonite clay catalyst (Ferris and Ertem [1992](#); Huang and Ferris [2006](#)), that in the presence of a polynucleotide template (Inoue and Orgel [1983](#)). Normally, the condensation of the activated nucleotide monomers provides oligonucleotides with an average length of ten units in the presence of metal ion catalyst or clay mineral catalyst. Besides, spontaneous condensation of the activated nucleotide by continuous addition of the activated nucleotide in the presence of ▶ [montmorillonite](#) clay results in the formation of oligonucleotides up to 50-mer in length (Ferris et al. [1996](#)). On the other hand, oligoguanylates up to 40-mer in length form by the condensation of guanosine 5'-phosphorimidazolid on a polycytidylate template with Zn^{2+} ion, where the Watson-Crick hydrogen bonding directs the activated monomers of guanosine nucleotide on the template polynucleotide. However, this template-directed reaction is not efficient for the condensation of adenosine, uridine, or cytidine 5'-phosphorimidazolid on the complementary polynucleotide template. This is probably due to the fact that the template-directed formation of oligonucleotides is mainly supported by the stacking interactions between the activated nucleotide monomers rather than the Watson-Crick hydrogen bonding between the

activated nucleotide and the complementary template. At the same time, it has been confirmed that the replication of oligonucleotides partially proceeds from the mixture of four types of activated nucleotide monomers in the presence of mixed base template polynucleotides. Although the formation of oligonucleotide in the absence of the activated nucleotide is not considered to be successful, the possible pathway for the formation of oligonucleotide from nucleoside 3', 5'-cyclic monophosphate has been suggested recently (Costanzo et al. 2009).

[Peptide](#)

Definition

An oligopeptide is a short-chain peptide, i.e., a polymer of ▶ [amino acids](#) (AAs) connected by amide, or more precisely peptide, linkages. The term is usually limited to peptides with less than 20–25 amino acid residues.

Overview

In “peptides-first” scenarios for the emergence of biomacromolecules, oligopeptides capable of specific catalysis of some biological reactions (primitive metabolism) are suggested to have appeared without the previous existence of genetic material. For instance, in his protometabolic model, de Duve (1991) calls these short peptides “multimers.”

Chemically, the emergence of oligopeptides from preexisting amino acids poses several problems. The first two are consequences of chemical thermodynamics. The condensation of an amide bond between two AAs is thermodynamically unfavorable in solution, thus the amount of oligopeptide in an amino acid solution at equilibrium falls quickly with the peptide chain length: for instance, a glycine solution with a total AA concentration of 0.5 M, at equilibrium, would contain only one molecule of 18-m per 100 km³.

In addition, the formation of oligomers from a mixture of different amino acids would likely

show little selectivity, i.e., all possible sequences would be randomly formed. Since the number of sequences increases exponentially with the peptide length, the probability of forming significant amounts of a specific oligomer is vanishingly low.

The last problem concerns the slow kinetics of oligomerization: at room temperature and moderate pH, completion of the reaction would take several centuries due to high activation energy barriers.

Several solutions have been proposed to allow the prebiotic emergence of oligopeptides with a reasonable probability:

- They could have formed in submarine hydrothermal vents: thermodynamic equilibria are displaced toward AA oligomerization in hydrothermal conditions, although probably not enough to give high peptide yields.
- Oligomerization could have been coupled to a thermodynamically downhill chemical process. This would involve the input of “high-energy molecules” (more properly, molecules with high free enthalpies of formation) such as nitrogen oxides.
- Alternatively, it may have occurred in the “adsorbed state,” i.e., after adsorption of the AAs on mineral surfaces (“polymerisation on the rocks,” Orgel 1998). This hypothesis connects well to “surface metabolism” scenarios (e.g., those of Wächtershäuser) and may solve the kinetic as well as the thermodynamic problem, since catalysis by surface groups is likely.

The last two scenarios have been shown empirically to result in the formation of oligopeptides up to the pentamers at least, even though molecular details remain sketchy. It is noteworthy that they are only successful in fluctuating environments, i.e., when coupled with variations of the macroscopic conditions such as wetting and drying cycles.

Olivine

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Keywords

Mars · The Moon · Stardust mission · Comet Wild 2 · Chondrites · Meteorites · Moderately refractory elements

Synonyms

[Peridot](#)

Chemical Formula

Mg_2SiO_4 (forsterite), Fe_2SiO_4 (fayalite)

Definition

Olivine is a magnesium-iron silicate mineral of the orthorhombic crystal system and belonging to the *nesosilicates* (i.e., composed of a single silica tetrahedra; see ► [Geological data](#)). The ratio of magnesium and iron varies between two endmembers of the solid solution series: forsterite (Mg-endmember) and fayalite (Fe-endmember). Olivine is a common mineral in mafic (basalt) and ultramafic (peridotite) magmatic rocks on Earth and ubiquitous in chondrites. At pressures corresponding to 400 km in the Earth, olivine transforms into its wadsleyite polymorph, which defines the roof of the transition zone.

Overview

Being composed of moderately refractory elements (Fe, Mg, Si), olivine is one of the silicate minerals that first condensed from the cooling Solar nebula. The pure forsterite endmember melting point is 1890 °C and the pure fayalite one has a melting point of ca. 1200 °C. The spectral signature of olivine has been detected in the dust disks around young stars (Draine 2003). Olivine is omnipresent in meteorites except for enstatite chondrites (dominated by pyroxene) and a few carbonaceous chondrites (Mason 1963). In chondrites and pallasites, polymorphs (minerals with the same chemical composition but different crystal structures) of the forsterite, such as wadsleyite and ringwoodite, can be commonly found.

Olivine occurs in Moon mare basalts (Meyer 2003). Spectra of the Martian surface from the Mars Global Surveyor Thermal Emission Spectrometer (TES) showed the occurrence of several outcrops of olivine-bearing rock in a 30,000-square-kilometer area located in the *Nili Fossae* region, northeast of *Syrtis Major* (Hoefen et al. 2003).

Analysis of Comet 81P/Wild 2 particles returned by the Stardust mission has revealed

abundant silicate grains that appear to have formed in the inner regions of the solar nebula (Brownlee et al. 2006). Particles similar to amoeboid olivine aggregates (AOAs) were discovered (Brownlee et al. 2006) together with CAIs (Simon et al. 2008). AOAs are lumpy, olivine-rich inclusions up to a few millimeters across, found in CV3 meteorites such as Efremovka, Leoville, and Vigarano (Ruzicka et al. 2012). The findings in Comet Wild 2 were very surprising because it is expected that comets form in the outer Solar system, where refractory elements such as Ca and Fe are depleted. The abundance of high-temperature nebular solids at the edge of the Solar system is strong evidence for massive outward transport of inner Solar system materials by a variety of nebular processes (Bockelee-Morvan et al. 2002). An alternative view is that the high-temperature components originated in the outer Solar system, perhaps inside transient Jupiter-mass objects that formed in the outer Solar system but were disrupted (Bridges et al. 2012).

Olympus Mons

Ernst Hauber

Deutsches Zentrum für Luft- und Raumfahrt (DLR) e.V., Institut für Planetenforschung, Berlin, Germany

Definition

Olympus Mons is the largest known ► [volcano](#) on ► [Mars](#) and in the entire ► [Solar System](#) (height above the Martian topographic datum: 22 km; height above surrounding plains: ~20 km; basal diameter: ~640 km). The flanks are covered by tube-fed and channel-fed lava flows and have slopes of typically ~3–5°, except for a steeper, up to 6 km-high basal scarp. The morphological analogy to terrestrial volcanoes (e.g., Hawaii, Galapagos) suggests that Olympus Mons is a basaltic shield volcano. A summit caldera has ~80 km diameter and developed in multiple stages over the last several hundred million years (Ma). Some lava flows are probably even younger (~10 Ma), indicating possible ongoing volcanism on Mars.

Definition

The term ‘omics technologies summarizes all shotgun-based molecular methods for studying biological molecules of cellular organisms and includes the technologies *genomics*, *transcriptomics*, *proteomics*, and *metabolomics*. It furthermore encompasses also subcategories of each of the aforementioned technologies like lipidomics as a subcategory for metabolomics.

History

The term ‘omics was coined fairly late (1990s) compared to the actual development of the different technologies themselves that it encompasses. For instance, the field of genomics began to attract interest of researchers already in the 1960s. In 2004 the term *metagenomics* was introduced to the literature (Tyson et al. 2004), followed by other meta’*omics* technologies in the years after. Meta’omics techniques such as metagenomics or metatranscriptomics do not focus on studying biological molecules of one organism rather of a community of organisms from, e.g., an environmental sample. Novel technologies developed around studying microorganisms have also led to many neologisms that include the term ‘omics, such as *culturomics* (Kambouris et al. 2018), but do not reflect the original meaning of the

terminology and are sometimes misleading due to ambiguity arising from overlaps with other areas of sciences.

Overview

Genomics as the first of all 'omics technologies deals with the analysis of genomic sequences, ideally a whole genome of a target organism (Blattner et al. 1997). Genomics includes the reconstruction of the sequence, gene prediction, and functional gene annotation. Transcriptomics in contrast is set out with the aim of analyzing the entire transcriptional pool of an organism culture including ribosomal RNA, transfer RNA, messenger RNA, and small RNA and is thus also termed genome-wide expression profiling. Comparative transcriptomics can, for instance, lead to important conclusions about the different genes that are expressed by cells under different conditions, for instance, comparing regular cells to cancerous cells (Rhodes and Chinnaiyan 2005). Proteomics deals with the analysis of the protein pool of cultured cells (Patterson and Aebersold 2003), enabling the conclusion which genes were expressed during the cultivation conditions. The basis for proteomics is genomics as the derived protein sequences are fragmented and need to be matched to a genomic database. For metabolomics all substrates and products (metabolites) of biochemical reactions from a cellular culture are measured and related to the metabolic pathways predicted from other 'omics technologies (Wu et al. 2005).

The basic methodological approach of all 'omics technologies is a shotgun approach, i.e., not a single gene, gene product, or metabolite is analyzed regarding its composition or relative abundance but the entire cellular pool of the respective molecules. Consequently, the initial step of each 'omic technology is extracting DNA, RNA, proteins, or metabolites from a cellular culture. In the next steps, the respective molecules are fragmented and/or chemically analyzed. The subsequent steps involve heavy computational lifting by assembling the fragments and/or comparing the derived information to

comprehensive databases, a research field termed bioinformatics.

In Astrobiology, genomics and transcriptomics have been applied to a variety of scientific tasks, mainly geared toward the understanding of genomic capacities of microorganisms or their responses to stress conditions. For instance, the analysis of the genome of *Bacillus pumilus* strain SAFR-032, an extremely resistant spore former, shed light onto its encoded DNA repair mechanism (Gioia et al. 2007). Another example is the genome-wide transcriptomic response of *Serratia liquefaciens* after exposure to simulated Mars conditions, which revealed an upregulation on many transporters, DNA repair mechanisms, and the translation machinery compared to regular cultivation conditions (Fajardo-Cavazos et al. 2018).

Onverwacht Group

Gary R. Byerly

Department of Geology & Geophysics, Louisiana State University, Baton Rouge, LA, USA

Keywords

Archean stratigraphy · Komatiitic volcanism · Large asteroidal impacts · Early life

Definition

The Onverwacht Group in the ► [Barberton Greenstone Belt](#) is a major stratigraphic unit comprising the lower part of the ► [Barberton Supergroup](#) (formerly Swaziland Supergroup) in South Africa and Swaziland. The Onverwacht Group is a predominantly volcanic sequence bounded by a number of major faults, and thus only minimum thicknesses and ages are known. Composite sections of the Onverwacht Group are 10–12 km in thickness and range in age from 3,550 to 3,270 Ma. Microfossils and stromatolites in carbonaceous cherts occur as sedimentary interbeds. Komatiitic volcanism was first documented in the Onverwacht Group. Eight large asteroidal impact layers have been found.

Overview

The Onverwacht Group in the Barberton Greenstone Belt is a major stratigraphic unit comprising

the lower part of the Barberton Supergroup (formerly Swaziland Supergroup) in South Africa and Swaziland (Viljoen and Viljoen 1969). The Onverwacht is a predominantly volcanic sequence bounded by a number of major faults, and thus only minimum thicknesses and ages are known. A generalized map of the greenstone belt, including the areal distribution of the Onverwacht, is found in Anhaeusser and others (1981), and a detailed map, revised stratigraphic nomenclature, and structural cross sections of the central greenstone belt are found in Lowe et al. (2012). Composite sections of the Onverwacht are 10–12 km in thickness and range in age from about 3,550 to about 3,270 Ma (Lowe and Byerly 2007) (Fig. 1).

As summarized in Lowe and Byerly (2007), the Onverwacht Group likely formed during three to four major tectonic cycles each of which resulted in major basaltic to komatiitic platforms followed by local development of dacitic volcanism linked to contemporaneous TTG plutonism along the southern, western, and northern margins of the greenstone belt. These tectonic cycles include progressively younger units from south to north. Four to five structural domains make up the Barberton Greenstone Belt. Each contains recognizable units of the Onverwacht Group but often with distinctive facies changes across the bounding faults.

The Onverwacht Group was likely assembled by a combination of tectonic and magmatic accretion. The southeastern most domains of the Onverwacht contain the oldest units, the Sandspruit Formation, consisting dominantly of komatiitic lavas, and the overlying Theespruit Formation, which includes komatiitic, basaltic, and dacitic lavas, the latter dated at 3,511–3,538 Ma. The overlying Komati Formation (Viljoen and Viljoen 1969), at 3,482 Ma (Dann 2000), is largely comprised of komatiites in the lower several kilometers but contains much more basalt and basaltic komatiite in the upper several kilometers. The 3.5 km-thick composite section of the Komati Formation contains no chert units and only a single thin dacitic ash bed. The Komati-Theespruit contact is everywhere represented by a major fault. Overlying the Komati Formation are the classic “upper Onverwacht formations” of

Onverwacht Group, Fig. 1 Stratigraphic and tectonic summary of the major units of the Barberton Supergroup (Lowe and Byerly 2007)

Viljoen and Viljoen (1969) – the Hooggenoeg and Kromberg Formations, each about 2 km in thickness. The Hooggenoeg is dominated by basalt and basaltic komatiite but contains five major chert units and is capped by a thick pile of dacitic volcanics (ca. 3,445 Ma). The Kromberg Formation along the west limb of the Onverwacht Anticline has a basal member of silicified volcanoclastics and carbonaceous and ferruginous banded cherts that are up to 400 m thick. These cherts contain what is arguably the best evidence for life in the Onverwacht Group. The basal unit of the Kromberg, K1e, has been dated at 3,416 Ma; the uppermost unit, K3c, at 3,330 Ma. Lowe and Byerly (1999) introduced two formations to the Onverwacht Group: In the south-central areas of the greenstone belt, the youngest unit of the Onverwacht Group is represented by the Mendon Formation, about 1 km thick, subdivided into six formal members, each with a chert unit capping a series of komatiitic flows. Each member of the Mendon Formation has a distinctive chemical composition (representing the most extreme komatiitic compositions found in the greenstone belt, with Al/Ti ranging from 5 to 100), and each chert has distinctive and correlative features, including volcanic ash beds, impact layers, and stromatolitic beds. In the northern areas of the greenstone belt, the 1–2 km thick Weltevreden Formation appears to be comparable in age to the Mendon Formation but is very different in its stratigraphy. Strata of the 2–3 km thick Weltevreden Formation have a very narrow range of komatiitic composition and nearly chondritic to slightly superchondritic Al/Ti. They contain remarkably fresh komatiites with fresh olivine and fresh glassy melt inclusions and thick deposits of komatiitic ash (Stiegler-Thompson et al. 2010). Several internal ages from the Mendon and Weltevreden Formations range from 3,300 to 3,270 Ma (Puchtel et al. 2013). De Wit and others (2011) offer a number of opposing perspectives on the geology of the Onverwacht Group.

Diagenesis, Archean weathering, metamorphism, metasomatism, and modern weathering have significantly modified the original igneous and sedimentary rocks of the Onverwacht. There

is nearly ubiquitous silicification of sediment in the Onverwacht. Carbonaceous matter, volcanic ash, ferruginous matter, and evaporitic materials are all subject to very early diagenetic or metasomatic silicification. Komatiitic lavas are in places highly silicified, likely by processes similar to those that act on sediment and likely at the Archean seawater-rock interface (Hanor and Duchac 1990). Metamorphism is rather uniform at lower greenschist facies for interior sections of the greenstone belt (Xie et al. 1997), although the lowest formations are only found in close contact with younger TTG plutons and typically display amphibolite facies metamorphic grade (Moyen et al. 2006).

Microfossils and microbial mats (Walsh 2010), organic matter (Tice and Lowe 2006), and stromatolites (Byerly et al. 1986) in Onverwacht Group sedimentary interbeds represent some of the most compelling evidence for early life on Earth. Microfossils include a variety of morphologies and sizes, suggesting a considerable diversity of early life in these early shallow-marine environments. Banerjee and others (2006) report the preservation of microbial biomarkers in pillow lavas from the Onverwacht. Recent studies have added isotopic and chemical analyses of individual microfossils (van Zuilen et al. 2007).

Komatiitic volcanism was first documented in the Onverwacht Group (Viljoen and Viljoen 1969). The discovery section and Komati-type section occur just north of the Komati River in the BGB. The Viljoen brothers studied both the lower and upper formations of the Onverwacht Group, but their work in demonstrating that komatiites represent lava flows is particularly important. Dann (2000) re-examined the Komati Formation, adding new detail to the volcanic architecture of this unit. Stiegler-Thompson and others (2010) further documented the widespread distribution of explosive komatiitic volcanism in the Onverwacht Group. The origins of komatiites, and particularly those of the Onverwacht Group, are debated in a series of publications using a variety of mineralogical, isotopic, and chemical information to support a wet-low temperature-subduction origin versus a dry-high temperature-plume origin (Parman et al. 1997; Robin Popieul et al. 2012; Puchtel et al. 2013).

Eight large asteroidal impact layers have been found in the Onverwacht Group (Lowe et al. 2003, 2014). Cr-isotope evidence has provided strong confirmation of the impact hypothesis. Each of these impacts was likely larger than the K/T impact, and several were likely comparable to other late-heavy bombardment impacts of the inner solar system that gave rise to the lunar maria. The impact layer in Hooggenoeg member H4c, the S1 impact layer, has been dated at 3,472 Ma and correlated with an impact layer of the same age in the Pilbara of western Australia (Byerly et al. 2002). A new impact layer has been identified in the lower Kromberg Formation and two other impact layers in the Mendon Formation.

Surface environments have been examined based on sedimentary cherts found within the Onverwacht Group (Tice and Lowe 2006). The lavas and sediments appear to have been deposited on a marine platform, with environments ranging from subwavebase to supratidal. Explosive volcanism resulted in significant deposits of airborne and wind-transported materials. Except for the latest stage of the Hooggenoeg Formation, when a large dacitic volcanic center evolved, topographic relief was low and resulted in the widespread distribution of units with only minor changes in thickness. At the end of Hooggenoeg time, enough relief was present that turbidites flanked the main volcanic center.

Oort Cloud

Jacques Crovisier
Observatoire de Paris, LESIA, Meudon, France

Keywords

Comets · Small bodies

Definition

The Oort cloud is a spherical cloud of ► [comets](#) surrounding the Solar System and extending out to heliocentric distances greater than 100,000 AU.

Overview

The idea of a distant reservoir of ► [comets](#), extending to the verge of the ► [Solar System](#), was already discussed by Giovanni Schiaparelli (1910) and Ernst Öpik (1932). The Dutch astronomer Jan Oort (1900–1992) pointed out in 1950 the need of such a reservoir to explain the continuous input of new long-period comets. He showed, from the data gathered by Van Woerkom (1948), that many long-period comets have their aphelia at more than 20,000 AU. This reservoir is now known as the “Oort cloud.”

The Oort cloud is supposed to be spherical, extending from 20,000 AU from the Sun to 200,000 AU (the limit of the gravitational influence of the Sun). It could comprise as many as 10^{12} comets.

These comets cannot be directly observed in the Oort cloud, being too far from the Sun to manifest any activity. Following perturbations by a nearby star (or by a hypothetical distant planet), they may be transferred to orbits bringing them close to the Sun, where they become active. Such “Oort-cloud comets” have random inclination over the ecliptic and belong to the family of “nearly isotropic comets.” The most famous of them is 1P/Halley.

Comets stored in the Oort cloud were not formed there. They were formed further inward in the Solar System (presumably in the Jupiter – Uranus region) and subsequently ejected to the outer Solar System following gravitational perturbations by the giant planets.

The Oort cloud contrasts with the alternate reservoir of comets, the ► [Kuiper belt](#), which is at the origin of Jupiter-family comets.

Opacity

Sylvia Ekström
Observatoire Astronomique de l'Université de Genève, Faculté des Sciences, Université de Genève, Versoix, Switzerland

Definition

Opacity measures the property of a medium to attenuate light. The opacity depends on the composition of the medium, its density, and temperature, but also on the wavelength considered. The *absorption coefficient* a_v (with units $[\text{cm}^{-1}]$) enters into the definition of the ► [optical depth](#). More often in astronomy, it is the mass absorption coefficient $\kappa_v = a_v/\rho$ (with units $[\text{cm}^2 \text{g}^{-1}]$) which is used.

The main sources of opacity in an astronomical context are:

- Electron scattering (at temperatures of the order one billion K).
- Electronic transitions (free-free, bound-free, or bound-bound at temperature of the order 10,000 K).
- Molecular or dust absorption (around or below 3000 K).

The opacity plays an essential role in radiative transfer, and thus in the energetic equilibrium of stars.

Opaline Silica on Mars

Ernst Hauber
Deutsches Zentrum für Luft- und Raumfahrt (DLR) e.V., Institut für Planetenforschung, Berlin, Germany

Definition

Opaline silica ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) occurs at several locations on ► [Mars](#), although the definitive identification is contentious. The confirmed finding would indicate past aqueous activity. Aqueous free silica is a product of ► [basalt](#) weathering, when the interaction of water with mafic (i.e., Mg- and Fe-rich, silica-poor) ► [rock](#) rapidly dissolves olivine, pyroxene, and glass. Opaline silica could have been precipitated in hydrothermal or lacustrine (related to a lake) evaporitic environments on Mars. On Earth, it rarely persists more than a few million years, because it rapidly transforms into microcrystalline quartz during ► [diagenesis](#). The persistence of opaline silica on Mars over much longer geologic timescales (billions of years) indicates that water was not present for extended periods of time.

Oparin's Conception of Origins of Life

Stéphane Tirard

Faculté des Sciences et des Techniques de Nantes,
Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Nantes, France

History

In 1924, Alexander Ivanovitch Oparin (1894–1980), a young scientist in vegetal physiology, published in Moscow a very important text about the origin of life. With this text, he began a very long career devoted to this topic. He wrote important books and developed very active experimental researches.

He published this first text, entitled *Origins of Life*, in Russian. He described the evolution of earth and the transformation of matter from mineral molecules to organic molecules. Finally, according to him, little drops of organic matter could appear, which constituted the last step before becoming cells.

In 1936, Oparin published an important book entitled *Origins of Life*. In an interdisciplinary approach, he suggested a broad scenario of the origins of life on Earth, describing all the steps of the evolution of the Earth, of matter, and of primordial life. This book knew a great success and was translated into several languages, and especially into English in 1938.

This book is an exhaustive presentation of Oparin's ideas, very close to his 1924 conception. However, he introduced a lot of current scientific data and two specific points have to be underlined. Firstly, Oparin introduced the notion of coacervate coming from Bungenberg de Jong's work. Coacervates were microscopical vesicles formed in colloidal solutions and Oparin used them as a model of a primitive cell in his theory. Secondly,

Oparin claimed that the primitive atmosphere did not contain CO₂, and that it was reductive.

After the Second War, this book still was a point of reference. For example, John Desmond Bernal (1901–1971) quoted it (1951). In 1952, Harold Clayton Urey (1893–1981), the American physicist, wrote a synthesis on the primitive conditions and referred to Oparin (1938) about the lack of CO₂ in the primitive atmosphere and agreed with the Soviet scientist on this point.

During the following three decades, Oparin, who had important academic positions in the USSR, continued to be the leader of this topic in his country. He particularly worked on primitive metabolism and developed a heterotrophic hypothesis on the origin of life on Earth. However, in the lyssenkoist context, he neglected to work on heredity molecules.

Open Cluster

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

An open star cluster is a loosely bound group of a few 10³ stars formed from the same giant

molecular cloud and thus having the same age and ► [metallicity](#) (chemical composition). This property makes them valuable tools for the study of stellar evolution. Contrary to ► [globular clusters](#), open clusters are relatively young (less than a few 10^8 years old) and they are found in the plane of the Milky Way. About a thousand open clusters are known in the galaxy, but their total number may be ten times higher. The best known example is the Pleiades (10^8 year). Various processes (tidal interactions with giant molecular clouds and spiral arms) tend to disperse its members and dissolve an open cluster.

Operon

Carlos Briones
Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Synonyms

[Polycistronic transcript](#)

Definition

An operon is a group of genes whose products have related or complementary functions and which are transcribed as a unit. Polycistronic or multi-genes are then independently translated by ribosomes into the individual, functionally related proteins. Many bacterial and archaeal genes are organized

into operons, while they are exceptional in eukaryotes. The operon model was proposed by F. Jacob and J. Monod in 1961 to explain the coordinated regulation of co-transcribed genes involved in the metabolism of lactose in *Escherichia coli*. The so-called *lac* operon spans about 6000 nts and includes a promoter, an operator, three adjacent structural genes coding for the enzymes required for lactose metabolism, and a terminator. Regulation of the *Lac* operon was the first complex genetic regulatory mechanism to be elucidated.

Ophiolite

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble, France

Definition

An *ophiolite* is a slice of oceanic crust and underlying mantle that is thrust onto a continent by obduction. The stratigraphic sequence observed in an ophiolite corresponds to the layering observed of oceanic crust (from top to bottom): an upper layer of oceanic siliceous or carbonate sediments; a layer of pillow basalt followed by a layer of sheeted near-vertical diabase dykes; layers of gabbro and plagioclase or mafic cumulates; and a basal layer of “tectonite,” the deformed harzburgite (a type of peridotite) of the uppermost mantle. Many ophiolites contain only some of these lithologies. Debate surrounds the question of whether any ophiolite represents normal oceanic crust formed at mid-oceanic ridges. The geochemical compositions of basalt indicate that many ophiolites are

segments of crust that formed in back-arc basins (extensional zones on the edge of the continent at subduction zones). Reactions between water and ophiolite at high temperatures (300 °C) can produce low-molecular hydrocarbons by abiotic Fischer-Tropsch-type reactions during serpentinization.

Optical Depth

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Synonyms

[Optical thickness](#)

Definition

The optical depth is a dimensionless quantity, generally noted τ , that measures how absorbing – or ► [scattering](#) – a slab in a medium is, for an electromagnetic wave that propagates in this medium. Despite the term *optical*, this quantity does not refer to visual radiation only, but to any type of electromagnetic wave (from gamma-rays to radio). Depending on whether $\tau < 1$ or $\tau > 1$, a slab of medium is said to be optically thin or optically thick. In a medium of constant

density, the optical depth is proportional to the thickness of the slab.

In an absorbing medium, the intensity of inward radiation decreases as $\exp(-\tau)$ along the path it travels. In an emitting medium, such as a stellar ► [photosphere](#), or a planetary atmosphere in the infrared, the outward radiation is often well approximated by assuming that it comes entirely from the layer seen at optical depth $\tau = 1$ (Barbier-Eddington approximation).

Examples of media where the notion of optical depth applies: clouds of gas and dust in galaxies (visible, near-IR), stellar atmospheres (gamma-rays, visible), neutral or ionized interstellar medium (radio), planetary atmospheres (UV, visible, infrared).

Definition

OGLE (Optical Gravitational Lensing Experiment) is a collaboration of primarily Polish

astronomers that uses wide-field temporal photometric monitoring to study a broad range of astrophysical phenomena. The original goal of the OGLE collaboration was to search for dark matter with the gravitational microlensing technique. However, since its inception, OGLE has also played a central role in the search for exoplanets with microlensing. In addition, OGLE identified the first transiting planets found by photometry (as opposed to radial-velocity planets) and has contributed to the study of variable stars, Galactic structure, strong gravitational lenses, and ► [Kuiper belt](#) objects. OGLE project has gone through four phases. Phase III (2001–2009) was devoted to detecting gravitational microlensing effects and transiting planets. During this phase, OGLE project discovered several planets including ► [OGLE-2005-BLG-390Lb](#), the first super-Earth detected by the microlensing effect, and OGLE-2006-BLG-lb,c, the first multiple planet system detected by microlensing. Phase IV of OGLE project started in 2010. The main goal of this phase is to increase the number of planet detection via microlensing. At the moment, 23 planets have been detected by the OGLE project.

The Principal Investigator of the OGLE collaboration is Andrej Udalski from Warsaw University. The OGLE 1.3-m telescope is located at the Las Campanas Observatory in Chile.

Orbit

Avi M. Mandell

NASA Goddard Space Flight Center, Greenbelt, MD, USA

Keywords

Gravity · Kepler · Newton

Definition

The orbit of a celestial body is its path around a central mass, caused by the acceleration due to the gravitational force between them. The planets and minor bodies such as asteroids and comets in the Solar System orbit the Sun, while any celestial body in the Solar System that orbits something other than the Sun is called a satellite (moon). Long-term orbital motion is affected by the gravitational forces due to all bodies in the vicinity, as well as to torques due to forces such as gas drag, ► [dynamical friction](#), and radiation pressure.

History

The concept of a celestial orbit can be generalized to include any motion of a celestial body around another body and dates back at least to the earliest written texts. However, Johannes Kepler was the first to establish the true qualitative characteristics of astronomical orbits, formulating his three laws of planetary motion between 1609 and 1619. Analyzing the results from painstaking observations of the motions of astronomical bodies by Tycho Brahe over many years, he determined that these bodies travel on elliptical orbits (with the Sun at one focus), speeding up as they approach the Sun and then slowing down as they move farther away. As simple as they seem today, these two conceptual breakthroughs revolutionized the Western world's view of the structure of the universe. Until this time, the majority view was that the Sun, planets, and star all revolved around the Earth; this theory is known as geocentrism, with the most well-known proponent being the second-

century Greco–Roman philosopher Ptolemy. Heliocentrism, the idea that the orbits of the planets are centered on the Sun, had first been proposed by Aristarchos of Samos in the third century BCE but was largely ignored until it was explored by Copernicus in 1543 and later supported by Galileo’s observations of the motions of Jupiter’s moons. However, these early models conceived the orbits as perfect circles and therefore required many ad hoc additions to fit the observed motions of planets in the sky. Kepler’s realization that the orbits could be elliptical turned heliocentrism into a viable predictive theory.

Kepler’s third law that the square of the period of a planet’s orbit is proportional to the cube of the distance from the Sun ($P^2 \propto a^3$) provided the first mathematical relation between two orbital quantities and formed one of the primary drivers for Isaac Newton’s derivation of the inverse square law of universal [gravitation](#) ($F_{\text{grav}} \propto 1/r^2$). Newton was able to show that two gravitationally bound bodies will orbit the center of mass of the two-body system, and if the difference in mass is large enough, the smaller body will essentially orbit the more massive body. This simple mathematical formulation (with modifications included for general relativity as proposed by Albert Einstein) forms the backbone of all of celestial mechanics and dynamical astronomy.

Overview

As first envisioned by Newton, orbital shapes can be organized into three different categories based on how much energy the orbiting body has: elliptical (including circular), parabolic, and hyperbolic. Parabolic and hyperbolic orbits are unbound, in that they begin and end at an infinite distance from the center of mass; the difference between the two is that a body on a parabolic orbit has zero net energy, while a hyperbolic orbit requires a positive total energy and therefore has a nonzero beginning and ending velocity. Newton realized that these shapes correspond to sections of a cone (conic sections), with one focus of the orbit lying on the rotational axis of the cone. The

conic section therefore confines the orbital motion to a two-dimensional plane, known as the orbital plane.

Basic Methodology

It is important to start with a discussion of terminology, since the language of celestial mechanics (the name for the study of orbital dynamics) can become very confusing due to the many specialized terms used to describe the properties of an orbit.

The general terms for the closest and farthest points of an orbit are the periapsis and apoapsis; these terms can be specialized for individual situations (i.e., perigee for orbits around the Earth, perihelion for orbits around the Sun, and periastron for orbits around any star). The line that connects the periapsis and the apoapsis is called the line of apsides; this line naturally passes through the central body, and the direction of the periapsis can rotate to trace a circle if the orbit is perturbed (known as apsidal precession).

The motion of an orbiting body can be described by six quantities known as orbital elements. These quantities can be coordinates of position and velocity, such as the Cartesian coordinates of a body in a specific reference frame, but more commonly orbits are described using the Keplerian orbital elements, since these are independent of a specific reference direction. The six Keplerian elements are the semimajor axis and eccentricity of the ellipse, and the inclination, argument of periapsis, longitude of the ascending node, and either the mean (temporal) or true (angular) anomaly (see Fig. 1). The most useful and general elements are semimajor axis, eccentricity, and inclination, which describe the size, shape, and tilt of the orbit with respect to the reference orbital plane (the plane of reference in the Solar System is known as the [ecliptic plane](#)). The semimajor axis is defined as one half of the major axis of the orbital ellipse; note that this is different than the distance to the central body when the orbit is not a circle. The eccentricity describes how elliptical the orbit is, ranging from 0 for a circular orbit to 1 for a parabolic orbit.

Orbit, Fig. 1 A diagram of an orbit, with several orbital elements labeled (inclination, argument of periapsis, longitude of the ascending node, and true anomaly). The additional orbital elements not labeled are the semimajor axis (i.e., size of the orbit) and the eccentricity (i.e., ellipticity) of the orbit (WikiCommons)

The inclination of the orbit is measured in degrees, ranging from 0° to 180° (values larger than 90° indicate a “retrograde” orbit such that the object moves in the opposite direction around the star). The other elements are less intuitive and less frequently used, since they primarily define a single orbital position and average out to zero for a population of randomly oriented bodies (as opposed to eccentricity and inclination that have a characteristic distribution for a randomized population), and they will not be discussed in detail here.

There are a number of processes that can lead to an evolution of the orbital parameters of a single body or a population of bodies; these effects are known as perturbations. These perturbations generally fall into two categories: gravitational perturbations due to interactions with other bodies in the system (such as secular perturbations or dynamical friction) or relatively steady-state forces that either add or remove energy from the orbit (such as gas drag or radiation pressure). Gravitational forces between two bodies will lead to an excitation of the orbit of the smaller body (such as the scattering of comet-sized bodies into the ► [Oort cloud](#) by Jupiter) and a damping of the orbital excitation of the larger body (such as the damping of planetary eccentricities during ► [planet formation](#) due to interactions with small planetesimals).

Applications

The study of orbital dynamics is fundamental to much of planetary astronomy in our own Solar System, as well as the study of other stellar and planetary systems. We deduce the orbital motions and positions of bodies in our own system by studying the proper motion of objects as they move across the sky over time – the same method has been used since classical times – and we are still using it to discover ► [Kuiper Belt](#) objects at the far reaches of the Solar System today. In other planetary systems, we can measure the radial velocity of the central star and use that motion to calculate the orbital motion of surrounding planets even when they are impossible to detect directly.

We can also explore the evolution of the orbits of bodies in planetary systems over time using computer simulations. Computational numerical simulations of planetary dynamics all aim to solve the same general problem: how to calculate the gravitational and nongravitational forces on a system of bodies accurately over long timescales (known as the n-body problem). The solution to the dynamical evolution of any system of three or more bodies cannot be solved exactly, but there are many different types of mathematical algorithms that have been developed to optimize the pursuit of an approximate solution (i.e., Runge–

Kutta, symplectic integration, etc.). Important applications for these tools include the study of the formation of planetary systems through long-term accretion of ► [planetary embryos](#), as well as the dynamical history of populations of small bodies in our Solar System (such as the Kuiper Belt).

Orbital Period

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

The orbital period (P) is the time required for a body to complete an orbit around a central mass. The orbital period can be calculated by Kepler's third law, which in the solar system takes the form

$$P^2 = a^3$$

where P is in years and the orbit's semimajor axis a is in AU. For different stellar masses the full equation that should be used is

$$P^2 = \frac{4\pi^2 a^3}{G(M_{\text{star}} + M_{\text{p}})}$$

where M_{star} and M_{p} are the stellar and planetary mass, respectively, and G is the gravitational constant.

Orbital Resonance

Jérôme Perez
Applied Mathematics Laboratory, ENSTA
ParisTech, Paris, France

Keywords

Gravitation · Instability · Period · Orbits

Definition

An orbital resonance is either a stabilizing or a disrupting phenomenon produced by the cumulative effect of gravity between at least two bodies in periodic orbits, generally around a third, more massive body.

Overview

The motion of a body in a fixed gravitational field is described by an ordinary differential equation. The solution of this problem is entirely determined provided we know its initial conditions.

In several physical cases, this solution has some periodic characteristics. The period of such a periodic motion depends essentially on a mean distance between bodies in gravitational interaction. For the two-body Keplerian problem, this is Kepler's third law: The square of the ► [orbital period](#) is directly proportional to the cube of the ► [semi-major axis](#) of its elliptical orbit (see ► [Gravitation](#)).

If several bodies are in orbit in a fixed gravitational potential and the ratio of the periods of two of these particular motions is rational (ratio of two integers), a special configuration occurs periodically. The cumulative effects of this configuration could be favorable for reaching a stabilized state or, on the contrary, could lead to a destructive process of the system or of part of it, by ejection of one or several of the bodies.

The solar system contains plenty of orbital resonances.

Between Mars and Jupiter, there exist thousands of small bodies that form the asteroid belt. In 1866, Kirkwood announced the discovery of gaps in the distances of these bodies' orbits from the Sun. These gaps were located at positions where, if there were a body, its period of revolution around the Sun would be an integer fraction of Jupiter's orbital period. In fact, these gaps were dug by orbital resonances. Likewise, Mimas, a minor satellite of Saturn, has a period that is twice the one of a body which would be orbiting at the location of the Cassini division seen in the Saturn's ring.

Sometimes resonances can maintain rather than exclude bodies from a peculiar orbit. Io, Europa, and Ganymede, the first three moons of Jupiter, show a special kind of orbital resonance called Laplace's resonance: their orbital period are in the ratio 1:2:4. In consequence, these three moons cannot be aligned together on the same side of Jupiter. This configuration could eject one of them.

Organic Dust, Influence on the Origin of Life

Sun Kwok
Faculty of Science, The University of Hong Kong, Hong Kong, China

Keywords

Origin of life · Earth, external delivery of organics · Stellar evolution

Definition

This topic considers the possibility that organic dust particles of extraterrestrial (interplanetary, stellar, or interstellar) origin played a role in the origin of life on Earth.

History

Current theories on the ▶ [origin of life](#) are centered on the hypothesis that under suitable conditions (e.g., a primordial soup), simple

molecules can be synthesized into complex organic compounds which later develop into self-replicating living organisms. An initial laboratory basis for this hypothesis was the Miller-Urey experiment, in which a mixture of gaseous molecules (hydrogen, water, ammonia, methane) when subjected to electric discharge yielded complex organics such as amino acids. The discoveries of insoluble organic matter in carbonaceous meteorites (Cronin et al. 1987), organic contents in interplanetary dust particles (Flynn et al. 2003), and complex organic dust synthesized by stars (Kwok 2004) have raised the possibility that externally delivered organics may have allowed the origin of life on Earth to bypass some of the first steps of organic synthesis on the early Earth (Ehrenfreund et al. 2006; Kwok 2009).

Overview

Isotopic analysis of carbonaceous meteorites has also discovered the presence of presolar grains, ▶ [star dust](#) that is made in the asymptotic giant branch of stellar evolution and ejected into the ▶ [interstellar medium](#) by stellar winds (Zinner 1998). The fact that one can actually hold star dust in our hands is proof that star dust can travel across the Galaxy and reach our Solar System intact. The fact that organic matter in Solar System objects has been found to have hydrogen isotopic ratios that differ from the terrestrial D/H ratio also suggests that there is interstellar organic dust in the Solar System (Ehrenfreund et al. 2002; Nakamura-Messenger et al. 2006; Sandford et al. 2006).

Once arrived in our Solar System, these star dust particles have to find a way to Earth. The most commonly discussed mechanism of delivering extraterrestrial organic dust to the early Earth is through the Late Heavy Bombardment (Chyba and Sagan 1992). The frequent collisions between the Earth and asteroids and comets during the early times of the Solar System imply that a significant amount of external organic materials could be delivered to Earth (Ehrenfreund et al. 2006). Alternatively, the Earth, formed

through the process of aggregation, may have contained a significant amount of primordial organic material. Since the organic star dust has a structure similar to that of ► [kerogen](#), the primordial organic matter could be extremely resilient and may have survived the formation of the Earth.

At this time, there is no direct evidence that the early Earth had been enriched/contaminated by a large amount of external organic matter. If it was, there is also not yet any evidence that this organic matter played any role in the origin of life. However, the possible implications can be significant. In the traditional endogenous origin of organic matter theories on the origin of life, the evolution to life could be a rare event due to unique circumstances of the Earth. However, in the external delivery hypothesis, life could be common in the Galaxy, as all planetary systems in the Galaxy could have been equally enriched by organic star dust.

Keywords

Star dust · Stellar evolution

Synonyms

[Organic grains](#); [Organic solid particles](#)

Definition

Organic dust consists of micron- or nanometer-sized carbon-based solid-state particles with aromatic (ring-like) and/or aliphatic (chain-like) structures. The solids could be in crystalline (periodic) form, or more likely, in amorphous (random) form. Possible examples of terrestrial counterpart are soot, which is a product of combustion of hydrocarbons in a flame, and ► [kerogen](#), the most common form of organics on Earth formed from decayed living matter.

History

The existence of interstellar dust has been known since the early twentieth century through the effect of selective extinction on the light of distant stars. The chemical composition of the dust particles was initially assumed to include graphite, iron, or ice. Development in stellar nucleosynthesis led to the understanding that the element carbon is synthesized in the asymptotic giant branch (AGB) phase of stellar evolution. This led to the suggestion by Fred Hoyle that carbon-based solid particles could be produced by stars (Hoyle 1955). The possibility that some of this star dust might be organic in nature was first suggested in the 1970s (Hoyle and Wickramasinghe 1977). Later, it was suggested that organic compounds can be detected in the infrared part of the spectrum through their C–H stretching mode (Knacke 1977; Duley and Williams 1979).

After the discovery of the ► [unidentified infrared emission \(UIE\)](#) bands, it was realized that some astronomical spectra resemble the spectral features observed in automobile exhaust. This led to the suggestion that the carriers of the UIE bands may be related to polycyclic aromatic hydrocarbon molecules (Allamandola et al. 1985). This represents the beginning of the serious studies of organic compounds in space.

Overview

Since organic solids can take on many different forms, the identification of a specific organic solid is not as straightforward as in the case for inorganic minerals. Minerals generally have highly ordered lattice structure in a crystalline form and therefore possess optically active lattice vibrational modes. These produce clear infrared spectral signatures, allowing the identification of exact minerals. Organic solids, however, have many electronic states, and their absorption bands are very broad. Macromolecular organic solids can be identified by their visible colors, albedo, and infrared bands. More specifically, the vibrational modes of various functional groups can be identified through comparison with laboratory spectra.

Amorphous carbonaceous solids are characterized by different sp^2/sp^3 hybridization ratios as well as mixed hybridization states. Organic particles of such structures are natural products of combustion. The first nucleation products for soot particles formed in flames have structures consisting of islands of aromatic rings linked by chains. Laboratory-synthesized carbonaceous nanoparticles are found by chemical analysis to consist of networks of chains and rings. Various laboratory experiments have been performed to simulate the synthesis of carbonaceous nanoparticles in stellar outflows. The products from vapor deposition are independent of energy injection techniques, which include laser ablation of graphite, laser pyrolysis of gases, arc discharge, microwave irradiation, UV photolysis, and flame synthesis.

By introducing hydrogen into familiar forms of carbon such as graphite (sp^2) and diamond (sp^3), a variety of amorphous C–H alloys can be created (Robertson 2002). Geometric structures of different long- and short-range order can be created by varying the aromatic-to-aliphatic ratio. The infrared spectra of these amorphous carbonaceous materials resemble the astronomical unidentified infrared emission bands seen in ► [planetary nebulae](#) and ► [protoplanetary nebulae](#) (Fig. 1). Since these amorphous carbonaceous solids have absorption bands in the visible, they can be easily excited by visible light from stars.

Many organic compounds, including hydrogenated amorphous carbon, exhibit photoluminescence, suggesting that photoluminescence by organic dust may be the source of the so-called extended red emission observed as a diffuse glow in some astronomical environments (Rusli and Amaratunga 1996).

Although carbon and hydrogen are the basic constituents of organic star dust, other abundant heavy elements such as nitrogen, oxygen, and sulfur are also likely to be present. These amorphous compounds are sometimes collectively referred to as CHONS.

Organic grains of similar structures have been found in the Solar System. The insoluble organic matter (IOM) in carbonaceous meteorites has

Organic Dust, Synthesis by Stars, Fig. 1

Laboratory infrared spectra of hydrogenated amorphous carbon (*top panel*) compared to the astronomical spectrum of the planetary nebula IRAS 21282 + 5050 (*bottom panel*). The laboratory spectrum is adapted from Dischler et al. (1983). Horizontal axis is in wavenumber (*inverse wavelength*). The red labels in the astronomical spectrum mark the unidentified infrared emission bands

mixed aromatic/aliphatic structures similar to those of terrestrial kerogen. Organic dust in the Solar System is generally assumed to be manufactured in the Solar System, although certain isotopic anomaly suggests that it could be of stellar or interstellar origin (Ehrenfreund and Charnley 2000).

Organic Material Inventory

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

The organic material inventory (sometimes just “organic inventory”) is a list of amounts and composition of spacecraft materials that contain organic compounds (defined as carbon-containing compounds *excluding* carbides, carbonates, cyanides, and simple oxides, but often *including* propellants) that are carried on a spacecraft in quantities above a specified amount. This inventory is a component of required ► [planetary protection](#) documentation for missions to target objects for which there is an interest in studying organic compounds that could contribute to understanding of the origin and evolution of life in the Solar System.

Definition

An organic molecule is any member of a large class of molecules containing carbon and then

limited by a number of somewhat arbitrary restrictions. For historical reasons, a strict definition of an organic molecule is difficult. The word “organic” dates back to the ancient Greeks. For centuries, many in the West believed in the concept of vitalism: that certain “organic” compounds could only be synthesized by the action of a vital “life-force” possessed only by living organisms. This implied that “organic” compounds were fundamentally different from the “inorganic” compounds, which could be obtained by laboratory manipulation.

The first well-documented experimental synthesis of an “organic compound” occurred in 1828 when Wöhler synthesized ► [urea](#) from the “inorganic” compounds potassium cyanate and ammonium sulfate. Urea had been considered an “organic” compound, as it was known to occur only in the urine of living organisms. Since then, many thousands of biological molecules have been synthesized by organic chemists.

Some sources define organic compounds as those containing C–H bonds; others include C–C bonds in the definition, still others merely require a molecule to contain carbon. This last definition would include compounds such as steel alloys and calcite, which most organic chemists would not consider part of their field of study. The C–H bond or C–C bond containing definitions would exclude urea and many other compounds commonly accepted by chemists as “organic.”

While the definition of what constitutes an organic compound can be ambiguous for a few small molecules such as urea, CO, and HCN, this is much less true for even slightly larger molecules. Indeed, today many millions of “organic” compounds have been synthesized by chemists, and the theoretical number possible is infinite. For example, the number of small organic molecules in what is considered the pharmacologically relevant size range (molecular weight $\sim < 500$ amu) is estimated by some to be on the order of 10^{60} .

Definition

The term Organometallic refers to compounds containing organic moieties bonded to a metal, often covalently. Many organometallic complexes feature coordination bonds between a metal and an organic ligand. The organic ligand often binds the metal through a heteroatom such as oxygen or nitrogen, in which case such compounds are considered coordination compounds. However, if any of the ligands form a direct metal–carbon bond, then the complex is usually considered organometallic. There are many naturally occurring organic coordination compounds. For example, the ► [protein](#) hemoglobin contains four ► [heme](#) groups in which an iron ion is coordinated to the nitrogen atoms of the porphyrin rings. Similarly, magnesium is coordinated via nitrogen atoms at the center of ► [chlorophyll](#). In contrast, the ► [coenzyme](#) methylcobalamin, which has a cobalt–methyl bond, is a true organometallic complex.

Origin of Life

Antonio Lazcano

Facultad de Ciencias, UNAM, Cd. Universitaria,
Mexico City, Mexico

Keywords

Emergence and complexity · Heterotrophic hypothesis · Oparin-Haldane · Prebiotic evolution · Primordial autotrophy · Spontaneous generation

Synonyms

[Abiogenesis](#); [Biopoesis](#); [Emergence of life](#)

Definition

In evolutionary biology, the phrase “origin of life” refers to the first appearance of living entities. If the emergence of the biosphere is seen as the evolutionary transition between the nonliving and the living, then it may be meaningless to attempt to draw a strict line between these two worlds, and the appearance of life on Earth may therefore be better envisioned as a continuum that seamlessly joins the prebiotic synthesis and accumulation of organic molecules in the primitive environment with the emergence of self-sustaining, replicative chemical systems capable of undergoing Darwinian evolution.

Overview

The term “origin of life” has several possible meanings, but from the perspective of

contemporary biology and within the framework of evolutionary theory, it refers to the first appearance of primordial living entities. It is generally assumed that since antiquity early philosophers and naturalists appealed to spontaneous generation to explain the origin of life. However, with few exceptions, this was not the case. Spontaneous generation was seen mostly as a nonsexual reproductive mechanism, and it was not until Erasmus Darwin, Georges Louis Leclerc de Buffon, and Jean-Baptiste Lamarck incorporated spontaneous generation within their transformist views that it was conceived as the mechanism that had led to the first appearance of life on our planet (Farley 1977).

Like his predecessors, Charles Darwin surmised that plants and animals arose naturally from primordial nonliving matter, but like many others, he rejected the idea that putrefaction of preexisting organic compounds could lead to the appearance of organisms. Darwin’s letters, notebooks, and few published statements on the issue demonstrate that although he favored the possibility that life could appear by natural processes from simple inorganic compounds, his reluctance to discuss it in public was due at least in part to the recognition that it was difficult to develop fruitful experimental approaches to address the problem. Nevertheless, his theory established the framework that would lead to a number of attempts to explain the origin of life by introducing principles of historical explanation (Peretó et al. 2009).

Panspermia: Past and Present

Darwin’s *Origin of Species* was published in 1859, the very same year in which Pasteur began the experiments that would lead him to disprove spontaneous generation of microbes. His results had implications that went well beyond the limits of academia. Since the times of Lamarck and Buffon, spontaneous generation had been associated in France not only with evolutionary theory but also with secular attitudes and radical political views. In such an entangled atmosphere, spontaneous generation embodied not only support for evolution and transformist views but also implied an anticlerical political stance (Farley 1977; Fry 2002; Strick 2009).

Pasteur's results made it difficult to explain the origin of life by means of spontaneous generation, a conclusion that was interpreted as a major blow to one of the implicit assumptions underlying Darwin's views. Several devoted materialists like Emil du Bois-Reymond, Karl von Nageli, and August Weismann continued to support the idea of spontaneous generation, but others, like Hermann von Helmholtz, felt that they could sidestep the issue by assuming that viable microbes had been delivered to the primitive Earth by meteorites, attempting to keep the validity of evolution. In fact, toward the end of the nineteenth century, the belief that life on Earth had evolved from extraterrestrial organisms elicited a number of proposed mechanisms that could have transported microbes between planets (see, e.g., Arrhenius 1908), but little attention was given to the central issue of their actual origin (Oparin 1924, 1938; Kammenga 1982; Fry 2002).

The recent revival of the panspermia hypothesis has not changed this situation. Recent proposals that terrestrial life arose elsewhere and was transferred to our planet are based on the well-established exchange of solid material among the different bodies in the solar system, the assumption of more benign environments in some of these other planets during the early stages of planetary system, and the surprising resistance of a number of prokaryotic species to environmental insults such as high fluxes of UV light or corpuscular radiation. Thus, the panspermia hypothesis has been recently restated in a variety of contexts. However, its current advocates, like those of the late nineteenth century, simply transfer the question of the origin of life to another habitable planet in our galaxy without providing an explanation of how it happened.

The Origin of Life: A Question Without an Answer?

A century and a half after Darwin admitted how little was understood about the origin of life, we still do not know when and how the first living beings appeared on Earth. Despite the seemingly insurmountable obstacles surrounding the

understanding of the origin of life, or perhaps because of them, there has been no shortage of discussion about how it took place. Since the attributes of the first living entities are unknown, it is not surprising that an inventory of current views on the origin of life reveals a mixture of opposites of every kind.

Looking back across time since the origin of life occurred is a scientific exercise fraught with guesswork, since the evidence required to describe the prebiotic environment and the nature of the events that led to the first living systems is scant and difficult to understand. Since most of the rocks from early Archean times that have been preserved have been metamorphosed to a considerable extent, there is no direct evidence of the environmental conditions on Earth at the time of the emergence of life, nor any fossil register of the predecessors of the first cells. There is no direct information of the chemical composition of the terrestrial atmosphere during the period of the origin of life, nor of other general and local environmental conditions, which may have been important for the appearance of living systems (Bada and Lazcano 2009).

Moreover, any explanation of the origin of living systems should attempt, at least implicitly, the definition of a set of minimal criteria for what constitutes a living organism. However, this has proven to be an elusive intellectual endeavor, though not for lack of trying. The absence of such a definition sometimes gives the impression that what is meant by the origin of life is described in somewhat imprecise terms and that several entirely different and even opposing questions are often confused (Lazcano 2008). Prior to the discovery of catalytic activity of RNA molecules, for instance, the origin of the genetic code and of protein synthesis was considered synonymous with the appearance of life itself. This is no longer a dominant point of view: four of the central reactions involved in protein biosynthesis are catalyzed by ribozymes, and their complementary nature suggests that they first appeared in an **▶ RNA world** (Yarus 2010), that is, that ribosome-catalyzed, nucleic acid-coded protein synthesis is the outcome of Darwinian selection

of RNA-based biological systems and not of mere physicochemical interactions that took place in the prebiotic environment.

Phylogenomics and Extant Metabolism Do Not Explain the Origin of Life

The variations of traits common to extant species can be explained as the outcome of divergent processes from ancestral life forms that existed prior to the separation of the three major biological domains, that is, the last common ancestor of Bacteria, Archaea, and Eukarya. This entity was likely far removed, if not in geological time, at least in complexity from the first living systems. Although no evolutionarily intermediate stages or ancient simplified versions of the basic biological processes have been discovered in contemporary organisms, the differences in the structure and mechanisms of gene expression and replication among Bacteria, Archaea, and Eukarya have provided insights into the stepwise evolution of the replication and translation apparatus, including some late steps in the development of the genetic code. Such comparative approaches have made it possible to distinguish the origin-of-life problem from a whole series of other issues, often confused, that belong to the domain of the early evolution of microbial life.

Molecular phylogenetic, comparative genomic, and bioinformatic approaches fail to provide direct information on the nature of the first living beings. A cladistic approach to the origin of life is not feasible, since all possible intermediates that may have once existed have long since vanished. Phylogenetic analyses based on comparative genomics provide important clues to early stages of biological evolution, but at the time being their applicability cannot be extended beyond a threshold that corresponds to a period of cellular evolution in which protein biosynthesis was already in operation, that is, the RNA/protein world (Becerra et al. 2007).

Although there have been attempts to deduce the nature of the first living systems from extant metabolism (Wächtershäuser 1988), there is a lack of simple continuity between the biosynthetic and the (possible) prebiotic pathways (Lazcano and Miller 1999). For instance, it is

likely that the ► [Strecker synthesis](#) and the Bucherer-Bergs reaction played a major role in the prebiotic accumulation of amino acids, but these abiotic routes are very different from transamination and the reverse Krebs cycle found in extant cells. The prebiotic synthesis of purines is from HCN and its derivatives and not from glycine, formate, and NH_3 , as in current biology. It is true that the aminoimidazole carboxamide ribotide in the de novo purine nucleotide biosynthetic pathway is comparable to the aminoimidazole carbonitrile formed in the prebiotic pathway, and a few other examples are found in the formation of uracil, glutamic acid, pyrroles, pyrimidines, and acetic acids (Lazcano 2010a). However, the similarities between these abiotic reactions and their enzyme-mediated counterparts in biosynthetic pathways do not necessarily indicate an evolutionary continuity between prebiotic chemistry and biochemical pathways, but may simply reflect chemical determinism. In other words, the few cases in which some extant metabolic pathways and prebiotic chemical processes share similar steps may be due to the unique way in which given reactions can take place.

From the Primitive Soup to the RNA World

It is generally believed that after Louis Pasteur had disproved the spontaneous generation of microbes using his famous swan-necked flask experiments, the discussion of life's beginning had been banished to the realm of useless speculation. However, scientific literature from the first part of the twentieth century shows the many attempts by major scientists to solve this problem. The list covers a rather wide range of explanations that go from the ideas of Pflüger on the role of HCN on the origin of life to those of Svante Arrhenius on panspermia and includes Leonard Troland's hypothesis of a primordial enzyme formed by chance events in the primitive ocean, Alfonso L. Herrera's sulfocyanic theory on the origin of cells, Harvey's 1924 suggestion of an heterotrophic origin in a high-temperature environment, and the provocative 1926 paper that Hermann J. Muller wrote on the abrupt, random formation of a single, mutable gene

endowed with catalytic and autoreplicative properties (cf. Lazcano 1992, 2010b).

In spite of their diversity, most of these explanations went unnoticed, in part because they were incomplete, speculative schemes largely devoid of direct evidence and not subject to fruitful experimental testing. Although some of these hypotheses considered life as an emergent feature of nature and attempted to understand its origin by introducing principles of historical explanation, the dominant view was that the first forms of life had been photosynthetic microbes endowed with the ability to fix atmospheric CO_2 and to use it with water to synthesize organic compounds. A major scientific breakthrough occurred, however, when Oparin (1924) suggested a heterotrophic origin of life that assumed that prior to the emergence of the first cells, a prebiotic synthesis of organic compounds led to the accumulation of the primitive broth.

Such ideas were supported not only by the evidence of organic compounds in meteorites but also by the striking nineteenth-century experimental demonstrations that biochemical compounds such as urea, alanine, and sugars could be formed under laboratory conditions, as had been demonstrated by Wöhler, Strecker, and Butlerow, respectively. Oparin's proposal, which was based on his Darwinian credence in a gradual, slow evolution from the simple to the complex, stood in sharp contrast with the then prevalent idea of an autotrophic origin of life. Since a heterotrophic anaerobe is metabolically simpler than an autotrophic one, the former would necessarily have evolved first. Thus, based on the simplicity and ubiquity of fermentative reactions, Oparin (1924) suggested in a small booklet that the first organisms must have been heterotrophic bacteria that could not make their own food but rather consumed organic material present in the primitive milieu.

These ideas were further elaborated and refined in a more extensive book whose English translation was published in 1938 (Oparin 1938). In this book, Oparin's original proposal was revised, leading to the assumption of a highly reducing milieu in which iron carbides of geological origin would react with steam to form hydrocarbons.

Their oxidation would yield alcohols, ketones, aldehydes, etc. that would then react with ammonia to form amines, amides, and ammonium salts. The resulting protein-like compounds and other molecules would form a hot dilute soup, in which they would aggregate to form colloidal systems such as coacervates, from which the first heterotrophic microbes evolved. Like many others at the time, Oparin did not address in his 1938 book the origin of nucleic acids, because their role in genetic processes was not even suspected. Because of this, inheritance of primordial genetic information was assumed by Oparin to be the result of growth and division in the coacervate drops he advocated as models of precellular systems (Lazcano 2010b).

Similar ideas were being developed independently by other researchers. In 1929, John B. S. Haldane, the extraordinary British polymath, also argued that the origin of life had been preceded by the synthesis of organic compounds. Based on experiments by E. C. C. Baly, an English chemist who claimed that he achieved the syntheses of amino acids and sugars by the UV irradiation of a solution of CO_2 in water, Haldane suggested that the absence of oxygen in a CO_2 -rich primitive atmosphere had led to the synthesis of organic compounds and the formation of a "hot dilute soup." Haldane was also influenced by d'Herelle's discovery of phages and suggested that viruses represented an intermediate step in the transition from the prebiotic soup to the first heterotrophic cells. Life may have remained, wrote Haldane (1929), in the viral stage for many millions of years before leading to the first cells.

The hypothesis that the first organisms were anaerobic heterotrophs is based on the assumption that abiotic organic compounds were a necessary precursor for the appearance of life. Experimental evidence in support of Oparin's proposal of chemical evolution came first from Harold C. Urey's laboratory, whom had been involved with the study of the origin of the solar system and the chemical events associated with this process. Urey had also considered the origin of life in the context of his proposal of a highly reducing terrestrial atmosphere (Urey 1952). The first

successful prebiotic amino acid synthesis was carried out with an electric discharge and a strongly reducing model atmosphere of CH_4 , NH_3 , H_2O , and H_2 (Miller 1953). The result of this experiment was a large yield of a racemic mixture of amino acids, together with hydroxy acids, short aliphatic acids, and urea. One of the surprising results of this experiment was that the products were not a random mixture of organic compounds; rather, a relatively small number of compounds were produced in substantial yield. Moreover, with a few exceptions, the compounds were of biochemical significance.

It is very unlikely, however, that the RNA world would have arisen from such abiotic organic syntheses. The discovery of catalytically active RNA molecules gave considerable credibility to prior suggestions that the first living organisms were largely based on ribozymes, a hypothetical stage called the RNA world (Gilbert 1986; Joyce 2002). This possibility is now widely accepted, but the problems involved with the synthesis and accumulation of RNA components suggest that ribozymes were not a direct outcome of prebiotic evolution, but may have been one of the evolutionary outcomes of what are now referred to as pre-RNA worlds. However, the chemical nature of the first genetic polymers and the catalytic agents that may have formed the pre-RNA worlds that bridged the gap between the prebiotic broth and the RNA world are completely unknown and can only be surmised.

The catalytic versatility of RNA molecules clearly merits a critical reappraisal of Muller's viewpoints (Muller 1961). However, the discovery of ribozymes does not imply that autocatalytic nucleic acid molecules ready to be used as primordial genes were floating in the primitive oceans or that the RNA world emerged completely assembled from simple precursors present in the prebiotic soup. The evidence supporting the presence of a wide range of organic molecules on the primitive Earth, including membrane-forming compounds, suggests that the evolution of membrane-bounded molecular systems preceded cellular life on our planet and that life is the evolutionary outcome of a process, not of a single, fortuitous event.

A Modern Scientific Battlefield

As summarized by Eschenmoser (2008), two major camps can be recognized among those working on the origins of life, that is, those assuming that the emergence of autocatalytic "metabolic" cycles on the primitive Earth was essential for the appearance of genetic systems and those that assume the priority of genetic polymers endowed with catalytic properties. These two different viewpoints reflect a rather sharp division between those who favor the idea that life is an emergent interactive system endowed with dynamic properties that exist in a state close to chaotic behavior and those who are reluctant to adhere to a definition of living systems lacking of a genetic component whose properties reflect the role that Darwinian natural selection and, in general, evolutionary processes have played in shaping its central characteristics.

With few exceptions, such as the views advocated by Sidney W. Fox and others (cf. Fox and Dose 1977), during the years that followed the Miller-Urey experiment, attempts to understand the origin of life were shaped to a considerable extent by the unraveling of the molecular details of DNA replication and protein biosynthesis. Perhaps not surprisingly, Herman J. Muller profited from the rapid developments in molecular biology and the success in prebiotic syntheses to update his gene-first proposal by arguing that what had emerged in the primitive oceans had been, in fact, a primordial DNA. For Muller and his followers, the essence of life lies in the combination of autocatalysis, heterocatalysis, and mutability, which he equated with evolutionary potential. In doing so, he implicitly stated that life could be so well defined that the exact point at which it started could be established with the sudden appearance of the first DNA molecule (Muller 1961).

On the other hand, Wächtershäuser (1988) has argued that life started with the appearance of an autochemolithotrophic two-dimensional monomolecular layer bound to pyrite that lacked a genetic system. According to this proposal, the synthesis in activated form of organic compounds such as amino acid derivatives, thioesters, and keto acids is assumed to have taken place on the surface of FeS and FeS_2 in environments that resemble those

of deep-sea hydrothermal vents. Wächtershäuser's explicit adherence to Karl Popper's philosophical stance (Popper 1959) played a major role in shaping his ideas. The hypothetico-deductive system developed by Popper underlines at least in part Wächtershäuser's so-called methodology of retro-diction, which he has used to argue that "lines of descent can be traced back to the first archaic pathways." According to this scheme, chemoautotrophic carbon fixation took place by a reductive citric acid cycle, or reverse Krebs cycle, of the type originally described for the photosynthetic green sulfur bacterium *Chlorobium limicola*.

Wächtershäuser's insightful prediction that ferrous sulfide in the presence of hydrogen sulfide (H_2S) is an efficient reducing agent should not be underappreciated. Pyrite formation can produce molecular hydrogen, promote the formation of ammonia from dinitrogen, and can reduce a few organic molecules under relatively mild conditions. However, compared with the surprising variety of biochemical compounds that are readily synthesized in one-pot Miller-Urey type simulations, the suite of molecules produced under the conditions suggested by Wächtershäuser is quite limited. Wächtershäuser's proposal, which is part of a trend that assumes that genetic material was not essential for the origin of life, has been modified by Russell and Hall (1997) and Martin and Russell (2003), who have argued that a primitive version of the acetyl-CoA pathway existed within FeS-rich mineral boundaries.

Based on the hypothesis that core metabolic processes have not changed since the emergence of life, Morowitz (1992) has also argued that intermediary metabolism recapitulates prebiotic chemistry. He maintains that the basic traits of metabolism could only evolve after the closure of an amphiphilic bilayer membrane into a vesicle, that is, that the appearance of membranes represents the discrete transition from nonlife to life. According to his hypothesis, reverse Krebs cycle-dependent life appeared with "minimal protocells" formed by bilayer vesicles made up of small amphiphiles and endowed with pigments capable of absorbing radiant energy stored as a chemiosmotic proton gradient across the membrane.

Life as an Emergent Complex System

The development of metabolic approaches to the origin of life like that of Morowitz (1992) and his followers is increasingly based on complexity theories and self-assembly phenomena. The background of current metabolic views lies not in Oparin's proposals, but in the attempt to extrapolate to biology the deeply rooted tendency in physical sciences to search for all-encompassing laws that can be part of grand theory that can explain many, if not all, complex systems (Lazcano 2010a). These explanations of the origin of life are based on the idea that the emergence of autocatalytic "metabolic" cycles on the primitive Earth was an essential prerequisite for the appearance of genetic systems. According to this approach, life can be considered an emergent interactive system endowed with dynamic properties that exist in a state close to chaotic behavior. Some of these proposals reflect a reaction against the reductionism of molecular biology, as well as the adherence to all-encompassing views based on complexity theories and self-assembly that tend to be more popular among physical scientists than among biologists.

Of course, the many examples of self-organizing physical systems that lead to highly ordered structures demonstrate that, in addition to natural selection, there are other mechanisms of ordered complexity that operate. Self-assembly is not unique to biology and may indeed be found in a wide variety of systems, including cellular automata, the complex flow patterns of many different fluids, in cyclic chemical phenomena (such as the Belousov-Zhabotinsky reaction) and, quite significantly, in the autoorganization of lipidic molecules in bilayers, micelles, and liposomes. There are indeed some common features among these systems, and it has been suggested that "emergent properties" or "self-organizing principles" suffice to explain the origin of life with the emergence of self-organizing metabolic cycles that at first did not require genetic polymers.

The available evidence suggests that the origin of life and the onset of natural selection resulted from self-organization phenomena involving nonequilibrium physical and chemical processes that go beyond simple Newtonian

physics and that were based on the abiotic synthesis, stability, and accumulation of organic molecules endowed with differential reactivity, on nucleic acid self-assembly and chemistry, and the spontaneous assembly of prebiotic amphiphiles into micelles and bilayer membranes, among others (de Duve 2005; Lehn 2002; Budin and Szostak 2010). The many examples of self-organizing physical systems that lead to highly ordered structures suggest that, in addition to natural selection, there are other mechanisms of ordered complexity that may have played a role in the origin of living systems. The recognition that the emergence of life is the outcome of an evolutionary process constrained by the laws of physics and chemistry can lead to the acceptance that many properties associated with living systems, such as replication, self-assembly, or nonenzymatic catalysis are also found in nonliving entities (Lazcano 2010a, b). Moreover, if the origin of life is seen as the evolutionary transition between the nonliving and the living, then it is meaningless to attempt to draw a strict line between these two worlds and the appearance of life on Earth should, therefore, be seen as an evolutionary continuum that seamlessly joins the prebiotic synthesis and accumulation of organic molecules in the primitive environment, with the emergence of self-sustaining, replicative chemical systems capable of undergoing Darwinian evolution (Lazcano 2010a, b).

Conclusions

The remarkable coincidence between the monomeric constituents of living organisms and those synthesized in laboratory simulations of the prebiotic environment appears to be too striking to be fortuitous. Nevertheless, at the time being the gap between the primitive soup and the RNA world is discouragingly large. Life cannot be reduced to one single molecule such as DNA or a population of replicating ribozymes, but present-day biology indicates that it could not have evolved in the absence of a genetic replicating mechanism ensuring the stability and diversification of its basic components.

As shown by the work of Jack Szostak and his associates (Mansy et al. 2008), it is possible to overcome at least in part the intellectual dichotomy between those claiming that the appearance of the first life forms depended on informational oligomeric compounds, that is, the so-called genetic approach, and those that argue that it was based on autocatalytic metabolic cycles. Instead of engaging in arguments about when exactly life started, the recognition that it is the outcome of an evolutionary process constrained by the laws of physics and chemistry can lead to the acceptance that many properties associated with living systems, such as replication, self-assembly, or catalysis are also found in nonliving entities.

Perhaps we will never know exactly how life originated. As in other areas of evolutionary biology, answers to questions on the origin and nature of the first life forms can only be regarded as inquiring and explanatory rather than definitive and conclusive. This does not imply that all origin-of-life theories and explanations can be dismissed as pure speculation, but rather that the issue should be addressed conjecturally, in an attempt to construct not a mere chronology but a coherent historical narrative by weaving together a large number of observations and experimental results (Kamminga 1982).

des Techniques EA 1161, Nantes, France

Introduction

In ancient times, the question of the origin of life was often linked to cosmological myths. In most civilizations, mythological narratives described the formation of the world and the appearance of living organisms and humans. These myths were

often related to religion. In the West, from the sixteenth century, some scientific and philosophical considerations about the Universe were strongly in tension with religious dogmas (Giordano Bruno, Galileo Galilei, etc.). During the Enlightenment, notably with Buffon's works and the Kant-Laplace cosmogonic hypothesis, new conceptions of the history of the Earth led to the hypothesis of a world initially without life. At the beginning of the nineteenth century, Lamarck claimed the transformation of species and suggested that they begin with spontaneous generations. However, he did not develop the topic of the primordial beginning.

This entry is focused on the nineteenth and twentieth centuries. It describes firstly the birth of evolutive abiogenesis theories during the second part of the nineteenth century, secondly the formulation of the synthetic hypotheses with Oparin (1924, 1938), Haldane (1929), and Bernal (1947, 1951), and thirdly the development of prebiotic chemistry during from the 1950s.

The Birth of the Evolutive Abiogenesis Theories

After the formulation of Darwin's theory and the initial debate between Louis Pasteur and Félix Pouchet, and the subsequent abandonment of the spontaneous generation theory around 1860, the question of the origin of life on the Earth was completely modified. Scientists could conceive of a unique and simple primordial ancestor of all the tree of life, but admitted that this process is impossible in the current nature.

Two main ways of research were developed. Some scientists claimed a panspermian theory in which life was brought to Earth from space. Life would be a property of matter, eternal as the Universe itself. This theory was notably claimed by William Thomson and also, at the beginning of the twentieth century, by Svante Arrhenius. Finally, around 1910, the results of a young French biologist, Paul Bécquerel, strongly limited the likelihood of this theory. He showed that spores and seeds could not resist the drastic conditions of the spatial environment, and he argued

that the panspermian theory had to be abandoned. Indeed, during the twentieth century, the partisans of this theory were very rare.

The other way was evolutionary abiogenesis, and it will be the topic of this entry. This theory claimed that life results from a progressive evolution of matter. In 1859 Darwin said only a few words about the origin of life in his book *The Origin of Species*. He explained that life began with unique and very simple forms; however, he gave no more details in his book. In 1871 in a letter to his friend, the botanist Joseph Dalton Hooker, he suggested a short scenario for the origin of life characteristic of an evolutionary abiogenesis theory, which was also developed in various formulations during the end of this century. It would be very interesting to compare Darwin's theory with Herbert Spencer's, Thomas Huxley's, or Ernst Haeckel's one. All these theories admitted the idea of progressive evolution of matter. At the beginning of the twentieth century, these very theoretical hypotheses were complemented by experimental works in organic chemistry.

Between the Two Wars: The Period of the Development of Hypothesis

Two main texts from the 1920s and the 1930s are often presented as fundamental in the history of theories of the origin of life. Indeed, in 1924 Alexandre Ivanovich Oparin and then in 1929 John Burdon Sanderson Haldane independently proposed complete and interdisciplinary scenarios of the origin of life on Earth. These two texts presented the evolution of matter as included in the evolution of Earth. And this evolution of matter depends on the primitive conditions on Earth. The primitive atmosphere and the primitive ocean were the places of organic synthesis and of complexification of molecules that led to life.

Oparin continued this work during his entire career and wrote a very detailed book in 1936 (translated in English in 1938), where he gave a scenario founded on new data. He claimed that the primitive atmosphere contained no carbon

dioxide and was reducing. He suggested also that some microscopic globular entities, the coacervates, formed in solution under certain conditions and could be a good model for the primitive form of cells. We can also notice that Oparin's theory suggested a heterotrophic primitive metabolism. During his entire career, Oparin continued his researches on coacervates and metabolism, and, in the context of the Lysenkoist theories, he neglected to include genetic molecules in his theory.

We have to underline that during the 1930s and the 1940s, the astronomer Alexandre Dauvillier chose a theoretical way different from Oparin's, a theory based on a photochemical origin of life. Then, John Desmond Bernal's theory (presented in a lecture in 1947 and published in 1951) was very important and innovative. He notably claimed that clays could be a very good support for origin of life chemical processes, both for their catalytic properties and for their crystalline structure. If molecules are confined on clays, there is no problem of dispersion.

However, this period was characterized by hypothesis, and experiments were very rare. The time of prebiotic chemistry began in the 1950s.

The Development of Prebiotic Chemistry

Melvin Calvin inaugurated this period with an experiment in which he exposed carbon dioxide to γ rays. He produced formaldehyde and claimed that this result was very important for understanding the origin of life on Earth. We can admit that this experiment was the first in prebiotic chemistry. Indeed, Calvin claimed to respect prebiotic conditions of the primitive Earth in his protocol. For example, he introduced carbon dioxide because he was convinced that this gas was present in the primitive atmosphere.

Few months later, Harold Urey contested this result concerning the presence of carbon dioxide. The American physicist agreed with Oparin regarding the reducing nature of the primitive atmosphere (that is to say, without carbon dioxide), and he suggested experiments with methane. In 1953, a young chemist, Stanley Miller,

produced amino acids from a mixture of hydrogen, ammonia, methane, and water vapor exposed to electrical discharges during 1 week.

Calvin's and Miller's experiments were the first in prebiotic chemistry, because in their protocols they imposed the constraint of the supposed prebiotic conditions of the primitive Earth. From this moment, a lot of experiments would be realized in such conditions. During the 1950s and 1960s, specialists of prebiotic chemistry tried to synthesize various organic molecules, characteristic of different levels of complexity and corresponding to three steps of the supposed process of origin of life on Earth.

The first step concerned amino acid and sugar synthesis. A few years later, attention turned to the synthesis of DNA bases, and at the beginning of the 1960s to uracil, an RNA-specific base. It seems that the results of molecular biology indicated goals for prebiotic chemistry. Indeed during this period, DNA and RNA became very significant molecules in biology.

In 1958, Fox and Harada obtained thermopolymerization of amino acids in prebiotic conditions and called their product proteinoids. In 1965, again in prebiotic conditions, Fox produced microspheres with these proteinoids.

These different works characterized the three steps of the model that specialists of origin of life theories tried to build: the synthesis of little molecules (sugars, amino acids, bases, etc.), the synthesis of macromolecules, and then cells themselves.

Conclusion

It is important to underline that since the 1950s the development of the research on the origin of life is dependent of an interdisciplinary approach, which leads the theories and the experiments. Firstly, data concerning the primitive conditions on Earth, coming from geology and planetary science, defined experimental conditions. Secondly, the results of molecular biology, the role of protein, DNA, and later RNA, indicated some goals for prebiotic synthesis. Last but not the least, micropaleontology gave a time scale to the model,

indicating the maximal duration of the process of emergence of the first cells.

The last decades have confirmed the necessary interdisciplinarity of astrobiology, which is described in this encyclopedia.

[Diaminovaleric acid](#)

Definition

L-ornithine is a natural, biological, noncoded diamino acid (with α - and δ -amino groups).

Ornithine, Fig. 1

L-ornithine (Fig. 1) first isolated by Jaffé from chicken excrement in 1877, hence its name (from Greek: *opvις* (ornis) = bird). It plays a major role as a carrier compound in the metabolic urea cycle. Ornithine can be derived from glutamate and is used in the biosynthesis of arginine and is therefore indirectly coupled to protein synthesis in mammals. Polypeptides containing unprotected ornithines undergo spontaneous lactamization. L-ornithine is produced through alkaline hydrolysis of citrulline and L-arginine, that is, the reverse of the biosynthetic process or the same direction observed in the urea cycle. Both L- and D-ornithine have been tentatively identified in the Murchison meteorite (Meierhenrich et al. 2004) at a concentration of $\sim <5$ ppb.

Molecular formula: $C_5H_{12}N_2O_2$
Molecular mass: 132.2 g mol^{-1}

Definition

Orthologous genes (or orthologs) are a particular class of homologous genes. They are found in different species and have diverged following the speciation of the species hosting them. Therefore, orthologous genes in different species derive from a common ancestral gene found in the ancestor of those species. Given their common origin, it is often the case that orthologous genes have the same function in the different species, but exceptions are not rare. The best way to infer that genes from different species are orthologous is by reconstructing their evolutionary relationships using molecular ► [phylogeny](#). Conversely, because orthologous genes evolve in parallel with the diversification of species, they are markers of choice for the reconstruction of the evolutionary history of species using molecular phylogeny.

NASA New Frontiers mission that collected a sample of surface particles from Bennu, a carbonaceous near-Earth asteroid.

History

Asteroids are remnants from the earliest stages of solar system history (Michel et al. 2015).

Laboratory investigations of meteorites and interplanetary dust particles from asteroids reveal the nature of early solar system processes leading to terrestrial planet formation (Lauretta and McSween 2006). The presence in primitive meteorites of complex organic compounds has led to speculation that they could have seeded early Earth with prebiotic elements and molecules (Deamer 2020). However, meteorite samples are altered by the processes of ejection from their parent body, atmospheric entry, and contamination by terrestrial microbes. Studying the organic chemistry and geochemistry of a pristine carbonaceous asteroid sample is needed to understand the nature of extraterrestrial organic compounds. The purpose of the OSIRIS-REx mission was to sample a primitive, carbon-rich asteroid that represents the objects that may have brought prebiotic molecules and volatiles such as water to Earth (Pasek and Lauretta 2008).

Overview

OSIRIS-REx (Origins, Spectral Interpretation, Resource Identification, and Security–Regolith Explorer) was NASA's first asteroid sample return mission. The OSIRIS-REx spacecraft (Lauretta et al. 2017; Fig. 1) launched on September 8, 2016, from Cape Canaveral, Florida. It rendezvoused with its target, the primitive near-Earth asteroid (101955) Bennu (Fig. 2), on December 3, 2018.

The mission used the payload of scientific instruments aboard the spacecraft (Lauretta et al. 2017) to characterize the global surface of Bennu in detail and select a safe site for sample collection (Lauretta et al. 2021). The spacecraft collected a sample of loose rock and dust particles (Fig. 3) from the surface of Bennu on October 20, 2020, to return to Earth in 2023 for laboratory analysis.

Bennu is among the darkest objects in the solar system (~4.5% reflectance) and is spectrally classified as a B-type asteroid (a subtype of C-asteroids characterized by a relatively featureless, blue-sloped spectrum). It was chosen as the target of the mission in 2005 because its orbit

OSIRIS-REx, Fig. 1 Artist's conception of the OSIRIS-REx spacecraft descending to the surface of the asteroid Bennu to collect a sample of surface particles. The

spacecraft's sample acquisition mechanism is extended in front of it on a mechanical arm. (Credit: NASA/Goddard/University of Arizona)

OSIRIS-REx, Fig. 2 This mosaic of asteroid Bennu is composed of 12 images collected on December 2, 2018, by the OSIRIS-REx spacecraft's PolyCam instrument from a range of 15 miles (24 km). The images were obtained at a 50° phase angle between the spacecraft, asteroid, and Sun. (Credit: NASA/Goddard/University of Arizona)

made it highly accessible for spacecraft rendezvous and Earth return, and because its spectral properties indicated a carbonaceous, volatile-rich composition (Lauretta et al. 2015). Bennu is a

small (~500 m diameter) asteroid that likely originated by gravitational self-collapse of rubble generated by the catastrophic disruption of a much larger (~100 km diameter) parent asteroid in the inner main belt 900–2000 million years ago (Walsh et al. 2013).

OSIRIS-REx spacecraft-based visible and near-infrared spectroscopy confirmed that Bennu is carbon-bearing (Simon et al. 2020), and the spectra are consistent with the presence of both organic molecules (aromatic and aliphatic CH bonds; Kaplan et al. 2021) and carbonate minerals (Kaplan et al. 2020). The carbonates sometimes occur as meter-scale veins in host rocks, suggesting extensive hydrothermal alteration on the scale of Bennu's parent asteroid that persisted for thousands to millions of years very early in solar system history (Kaplan et al. 2020). Bennu is also globally hydrated, with water bound up in its dominant lithology, Mg-rich phyllosilicates (Hamilton et al. 2019; Simon et al. 2020). Sample analysis, beginning in 2023, will provide new insights into the nature of these materials and their availability for habitability and the origin of life.

OSIRIS-REx, Fig. 3 Spacecraft image of the OSIRIS-REx sample acquisition mechanism collected on October 22, 2020, after the sampling event. The sample collection chamber (center) appears dark owing to optical extinction

from collected particles. Some particles on the order of 0.1–1 cm in diameter can be seen escaping into space. (Credit: NASA/Goddard/University of Arizona)

The sample's pristinity was ensured by stringent cleaning protocols during spacecraft fabrication and careful mission design during spacecraft operations (Dworkin et al. 2018). Any contamination was thoroughly documented with both active and passive monitoring. The mission archived materials and witness plates during spacecraft fabrication, integration, and testing. A complete database of all materials, elements, and analyses of witness plates on the spacecraft was compiled. The spacecraft fabrication materials are archived as part of the sample collection at the NASA Johnson Space Center.

After the sample is returned to Earth, all samples, witness plates, and space-exposed hardware will be available to the worldwide scientific community through the NASA sample allocation process. Ongoing sample analysis by generations of scientists using cutting-edge tools and methods guarantees an enduring scientific treasure that only sample-return missions can provide.

Synonyms

[Osmolyte](#)

Definition

Osmolites or [compatible solutes](#) are organic molecules which are compatible with cell metabolism even at molar concentrations and play protective

roles in adaptation to extreme environments. Microorganisms also accumulate organic solutes for osmotic adjustment. Thermophilic and hyperthermophilic organisms accumulate alcohol phosphates (e.g., inositol-phosphates) as compatible solutes for thermal stabilization, something which does not occur in bacteria or archaea that grow at low or moderate temperature. Osmolites or soluble compatibles can be classified into three groups: poly-alcohol molecules (e.g., manytol), quaternary amines (e.g., glycine betaine), and amino acids (e.g., proline). Compatible solutes have been studied in vitro and have shown significant effects on biomolecules as stabilizers of native macromolecules (proteins or nucleic acid structures).

Osmotic Pressure

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

► [Water](#) diffuses through semipermeable [membranes](#) from low- to high-solute- concentration solutions. This process is known as osmosis. Osmotic pressure is the pressure produced on the semipermeable membrane of an organism by the difference in solute concentration between the internal and the external part of the cell. When the

solute concentration in the interior of the cell is as that of the medium, we say that the solution is isotonic, no diffusion takes place. Normally, cell systems develop in environments where the solute concentration is lower than the cytoplasmic solute concentration. In this case, water diffuses from the medium to the cytoplasm. Halophilic organisms grow in solutions where the solute concentration is much higher than the cytoplasmic one. In this case, there is a tendency for water to flow out of the cell to diminish the osmotic pressure on the membrane. This can produce severe problems for cells if they have no means with which to deal with it. Normally, halophilic organisms have cytoplasmic ► [compatible solutes](#), organic or inorganic, which try to compensate the high osmotic pressure generated by the ionic strength of the medium in which they develop.

Small Solar System bodies · Asteroids · Comets · Interstellar objects · Exoplanets

Definition

1I/‘Oumuamua was the first small object discovered on a hyperbolic orbit passing through the Solar System. Its characteristics – including its lack of observed activity in conjunction with its detected non-gravitational acceleration – remain challenging to explain.

Overview

1I/‘Oumuamua was discovered by the Pan-STARRS telescope on October 19, 2017 (Meech et al. 2017). Its discovery triggered excitement in the astronomical community and among the general public. Due to its inherent faintness and rapid orbital motion, the observing window for ‘Oumuamua was short and within a month of its discovery it was beyond the reach of ground-based telescopes.

While its physical nature remains debated (see discussion below), ‘Oumuamua’s measured characteristics are as follows:

- At the time of its discovery its orbit was hyperbolic, with an eccentricity of 1.2 and a v_{infinity} (velocity upon entering the Sun’s gravitational potential) of 26 km/s (Meech et al. 2017).
- Its photometric colors were observed by several groups to be broadly similar to those of volatile-rich small bodies in the Solar System (e.g., C- and D-type asteroids, cometary nuclei; Meech et al. 2017; Jewitt et al. 2017).
- It did not show any signs of outgassing or cometary activity to very stringent limits (see Table 1 of ‘Oumuamua ISSI Team et al. 2019).
- Its brightness varied by roughly an order of magnitude (by 2.5 astronomical magnitudes) on a roughly 8-h timescale but in a not-quite-repeating fashion.
- Its size and albedo were never measured directly. Infrared observations (non-detections) with the Spitzer Space telescope allowed Trilling et al. (2018) to place an upper limit on its albedo of 50%, although their most likely value was ~10%.
- Its orbit was not purely Keplerian. Non-gravitational acceleration was discovered by

Micheli et al. (2018) thanks to astrometric follow-up with the Hubble Space Telescope. This acceleration was pointed directly away from the Sun and was consistent with an r^{-2} radial scaling.

In the months after its discovery, a large number of papers studied ‘Oumuamua’s likely physical characteristics and its possible origin. The large photometric variations likely indicate a very stretched-out object (Meech et al. 2017). Analysis of the light curve combined with shape models suggests a flattened shape with a most likely aspect ratio of $\sim 6:6:1$, although a cigar-like shape of $6:1:1$ is also possible (Mashchenko 2019). The non-repeating nature of its brightness variations indicated that ‘Oumuamua was undergoing non-principal axis, or “tumbling” rotation (Fraser et al. 2018). Several possible processes can potentially explain the large axis ratio of ‘Oumuamua: these include erosion from many small impacts (Domokos et al. 2017), low-speed collisions among planetesimals (Sugiura et al. 2019), tidal disruption (Zhang and Lin 2020), and evaporation (Seligman and Laughlin 2020).

Several studies used the detection of ‘Oumuamua to estimate the number density of such objects in interstellar space. Ironically, a comprehensive study by Engelhardt et al. (2017) placed an upper limit on this number density using non-detections just a few months before ‘Oumuamua was discovered. Do et al. (2018) calculated a number density of $\sim 0.1 \text{ au}^{-3}$ of such objects. If interstellar objects have a top-heavy size-frequency distribution (SFD) like the observed asteroidal SFD or the SFD produced when planetesimals form via the streaming instability, then their mass density is in significant tension with the expected amount of mass that is expected to be ejected in planetesimals per star (Raymond et al. 2018a; Moro-Martín 2018). Resolving this issue likely requires a bottom-heavy SFD for interstellar objects, the implications of which remain to be put in context.

Galactic dynamics indicates that ‘Oumuamua is likely a young object. Its velocity upon entering the Solar System was only 9 km/s from the local standard of rest (LSR), far smaller than the stellar dispersion of $\sim 50 \text{ km/s}$. ‘Oumuamua’s galactic

motion is similar to that of stars younger than 1–2 billion years (Portegies Zwart et al. 2018), although it may be far younger and associated with the nearby Carina star-forming association with an age of only about 30 Myr (Hsieh et al. 2021).

‘Oumuamua’s astrophysical origins remain debated. Early models included a large number of exotic processes including ejection from binary star systems and fluidization and ejection due to stellar evolution, among many others (see ‘Oumuamua ISSI Team et al. 2019 for a review). One simple early model proposed that ‘Oumuamua was simply a leftover planetesimal from an exoplanet system that was ejected after a close encounter with a giant planet after first undergoing a tidal disruption event and losing its surface ice after repeated passages close to its star (Raymond et al. 2018b). That model could reconcile the volatile-rich appearance of ‘Oumuamua with its lack of outgassing and could roughly account for the number density by invoking a large number of tidal fragments.

Accounting for ‘Oumuamua’s measured non-gravitational acceleration has provided a number of challenges to models. If the outgassing needed to account for the non-gravitational acceleration came from a single, randomly placed jet then the outgassing should have spun the object to such a degree that it should have disrupted (Rafikov 2018). This problem is solved if the jet was not randomly placed but instead followed the Sun’s substellar point on ‘Oumuamua’s surface; models show that, under such an assumption ‘Oumuamua would not have disrupted but rather may have been driven to non-repeating rotation as observed (Seligman et al. 2019).

Analysis of ‘Oumuamua’s non-gravitational acceleration showed that sublimation of water cannot provide sufficient force to explain the observed non-gravitational acceleration (Sekanina 2019). This indicates that a comet-like model for ‘Oumuamua cannot be correct. Rather, matching the non-gravitational acceleration instead requires invoking exotic ices such as hydrogen or nitrogen ice. These ices are the foundation of two models for ‘Oumuamua’s origins. The first proposes that ‘Oumuamua is a hydrogen “iceberg” that formed in the extremely cold starless core of a molecular

cloud (Seligman and Laughlin 2020). The second proposes that 'Oumuamua is a collisional fragment of a Pluto-like exoplanet that was created and ejected during a dynamical instability in its host system (Desch and Jackson 2021; Jackson and Desch 2021). Each model can match 'Oumuamua's observed characteristics yet the two have drastically different implications for the formation of such objects.

'Oumuamua was also the subject of a media frenzy in 2018 and again in 2021 that was driven by astronomer Avi Loeb. Loeb had proposed that 'Oumuamua's non-gravitational acceleration was caused by radiation pressure from the Sun (Bialy and Loeb 2018) and suggested in popular articles and later a book that the object was of artificial origin. His proposal has been widely refuted by the scientific community as baseless (see 'Oumuamua ISSI Team et al. 2019).

The controversy regarding 'Oumuamua triggered several studies regarding how to sample or intercept unexpected, *once-in-a-lifetime* objects in the future. The Lyra project developed a space concept to intercept 'Oumuamua itself. The goal of the *Comet Interceptor* mission (Snodgrass and Jones 2019) – funded by the European Space Agency in 2019 – is to intercept a future long-period comet or interstellar object. The mission will have a spacecraft waiting in orbit around the Sun (at the Earth's L2 point) before its target is discovered. If such a spacecraft had been ready and waiting at L2 in 2017, and 'Oumuamua had been discovered a few months earlier, it could have intercepted 'Oumuamua (Seligman and Laughlin 2018).

and proteins found in the cytoplasmic membrane, it contains polysaccharides. It is a rather complex structure only found in gram-negative bacteria. The lipid and polysaccharides are linked to form a lipopolysaccharide complex. For this reason, the outer membrane is often called the lipopolysaccharide layer (LPS). In the outer membrane, LPS associates with several proteins to form the outer leaflet of the membrane. Lipoproteins are also found in the inner leaflet of the outer membrane and their function is to anchor the membrane to the peptidoglycan. In the outer part of the membrane lipopolysaccharides replace phospholipids. Thus, although the outer membrane can be considered a lipid bilayer, its structure and function is quite distinct from that of the cytoplasmic membrane. Although the major function of the outer membrane of gram-negative bacteria is structural, its components can produce toxicity to animals. The outer membrane has special types of proteins called porins, which are channels responsible for the permeability of small molecules. The periplasm is the space delimited by the outer layer and the cytoplasmic membrane of the gram-negative bacteria in which different important cellular functions are performed.

Outer Space Treaty

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

The “Treaty on Principles Governing the Activities of States in the Exploration and Use of Outer Space, including the Moon and Other Celestial Bodies,” the Outer Space Treaty (OST) for short,

is the legal framework of international space law. It was proposed to the UN by the USSR, the UK, and the USA in 1966 and ratified by those countries and 108 others (as of February 2021), while another 23 have signed the treaty but have not completed ratification.

The Outer Space Treaty establishes the general principles applicable to the exploration and use of outer space and applies to all activities of states parties in outer space, whether such activities are carried out by governmental or nongovernmental entities or individuals.

Article IX, second sentence of the OST states: “State Parties shall pursue studies of outer space, including the Moon and other celestial bodies, and conduct exploration of them so as to avoid their harmful contamination and also adverse changes in the environment of the Earth resulting from the introduction of extraterrestrial matter and, when necessary, adopt appropriate measures for this purpose,” which is the basis for the COSPAR planetary protection policy on which all subsequent recommendations and guidelines are based.

Outflow Channels

Ernst Hauber
Deutsches Zentrum für Luft- und Raumfahrt
(DLR) e.V., Institut für Planetenforschung,
Berlin, Germany

Keywords

Erosion · Flooding · Groundwater · Ice · Water

Definition

Outflow channels on ► [Mars](#) are large channel systems that emerge fully-sized from rubble-filled “chaotic” depressions, are generally tens of kilometers across and hundreds of kilometers long, and were formed by fluid flow of ► [water](#) from subsurface reservoirs.

Overview

Outflow channels were first detected on images from the Mariner 9 mission (Baker and Milton 1974). They are the strongest morphological evidence that large amounts of water once flowed on the Martian surface. Characteristic landforms of outflow channels are anastomosing (building a network of streams that both branch out and reconnect) channels, streamlined erosional “islands,” dry cataracts, and scour marks and grooves on the channel floors (Baker 1982). The closest terrestrial analog for outflow channels is the huge complex of anastomosing rock-cut fluvial channels in east-central Washington (USA). This so-called Channeled Scabland was first interpreted by J Harlan Bretz as the result of the catastrophic megaflooding derived from ice-dammed Pleistocene glacial lakes (e.g., Bretz 1923), an interpretation which challenged the conventional geologic wisdom of Uniformitarianism and was, therefore, heavily debated (Baker 2009). Uniformitarianism (as described by Bates and Jackson 1980) is the fundamental principle or doctrine that geologic processes and natural laws now operating to modify the Earth’s ► [crust](#) have acted in the same regular manner and with essentially the same intensity throughout geologic time, and that past geologic events can be explained by phenomena and forces observable today; the classical concept that “the present is the key to the past.” Many models of the formation of Martian outflow channels favor a catastrophic formation by the sudden release of large amounts of water from subsurface reservoirs. Pressurized aquifers might have existed below an impermeable frozen upper crust (the ► [cryosphere](#)), which was then cracked by the ascent of volcanic dikes (e.g., Head et al. 2003). Alternatively, outflow channels might have been eroded, at least partly, by glacial processes (Lucchitta 1982). Most, if not all,

outflow channels show evidence for a multistage formation with different phases of activity separated by geologically long periods of time. Outflow channel activity spans a long time, from $\gg 3.5$ Ga to geologically very recent times (Neukum et al. 2010). Outflow channels terminate into the northern lowlands of Mars and might have fed an ancient northern ocean (Baker et al. 1991), although this scenario is contentious.

Oxic

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Oxic is a term used to describe a condition, environment, or habitat in which oxygen is present.

Oxic Sediments

Oxygen · Redox · Diagenesis · Organic carbon · Microbes · Respiration · Pore waters

Definition

Pore waters within oxic sediments contain measureable amounts of dissolved oxygen. In general, pore water oxygen concentrations decline with depth due to organic matter degradation. The depth of oxygen penetration varies depending on the sedimentation rate, mixing processes, the flux and type of organic carbon, and the oxygen content of bottom waters.

Overview

Sediments at the seafloor are porous and poorly consolidated and thus readily allow diffusion of bottom waters and the dissolved gases that they contain into the sediment. With depth, sediments undergo compaction and eventually lose contact with overlying seawater. While sediment pore waters at or close to the sediment-water interface in the global ocean commonly contain dissolved oxygen, the concentration of oxygen declines with depth due to organic matter degradation.

Deposited organic matter is degraded at the seafloor and during burial in the sediments, with less than 1% surviving to become part of the rock record (Emerson and Hedges 1988). Aerobic respiration is the first pathway used by microbes for organic matter degradation, as it is associated with the largest free energy yield. As such, aerobic respiration is responsible for the majority of organic carbon remineralization in the oceans and sediments (Bender and Heggie 1984). At low dissolved oxygen concentrations ($<10\ \mu\text{M}$), the rate of aerobic respiration begins to decline, and anaerobic respiration processes may proceed with alternate electron acceptors (► “Suboxic Sediments”, this volume). Aerobic respiration tends to be most prolific at the sediment-water interface, but oxygen may be present in pore waters for centimeters or even meters below the sediment-water interface.

The depth of oxygen penetration in sediments is highly variable and is controlled by the chemical, physical, and biological setting. One major

control is the concentration of oxygen in overlying bottom waters. The concentration of dissolved oxygen in surface waters is set by atmospheric oxygen levels, as well as the solubility of O_2 gas in water, which is itself controlled by salinity and temperature. At depth in the water column, oxygen is consumed by respiration, but the rate of decline depends on the local carbon cycle and mixing rates. Oxygen levels in oceanic bottom waters vary from up to $300\ \mu\text{M}$ below polar surface waters to $<5\ \mu\text{M}$ below oxygen minimum zones in intense upwelling regions. Higher oxygen levels at the sediment-water interface increase the average depth to which oxygen can persist in the sediments.

Sedimentation rate exerts another important control on the depth of oxygen penetration, by influencing the amount of time organic matter remains exposed at or near the sediment-water interface (Fig. 1). Under the high sedimentation rates common in coastal and shallow shelf environments ($\sim 1\ \text{mm year}^{-1}$), organic matter rapidly loses contact with overlying bottom waters. Therefore, a relatively large fraction of organic matter is often buried in such sediments, and oxygen in pore waters is rapidly consumed (Fig. 1). In contrast, under the low sedimentation rates common in deeper water settings ($<0.01\ \text{mm year}^{-1}$), organic matter remains exposed to oxic bottom waters for longer (thousands of years), and so there is less organic carbon leftover to drive anaerobic heterotrophic communities in the sediments.

Mixing in shallow water environments can disturb any stratification, bringing anoxic sediments from a few centimeters depth back into contact with oxic bottom waters. Mixing may occur mechanically, for example, during storm events or, biologically, through bioturbation (Kristensen 2000). More intense mixing results in re-oxidation of reduced species and allows deeper oxygen penetration (Fig. 1). The properties of the sediments can influence the degree of contact between bottom waters and pore waters. For example, fine-grained sediments, such as mud, have a lower porosity and so limit diffusion of oxygen from bottom waters into pore waters. This facilitates a steeper

Oxic Sediments, Fig. 1 The depth of the oxic zone in sediments is partly controlled by the sedimentation rate, the flux of organic matter, and mixing processes. In general,

the oxic zone extends deeper into the sediments in pelagic settings where sedimentation rates and organic carbon fluxes are lower

oxygen gradient than coarse-grained sediments, such as sand.

The flux and type of organic matter is also an important variable. Large fluxes of organic matter, as are common in coastal environments, can result in more rapid consumption of the available oxygen in shallow sediments. Furthermore, organic matter varies considerably in terms of its reactivity, with phytoplankton-derived carbon easier to digest than terrestrial organic matter which contains more refractory plant lignin. All of these parameters contribute to the exposure time of marine sediments to oxic conditions.

Kristensen E (2000) Organic matter diagenesis at the oxic/anoxic interface in coastal marine sediments, with emphasis on the role of burrowing animals. Electron donor · Reducing agent · Reductive

Synonyms

[Combustion](#); [Corrosion](#); [Rusting](#)

Definition

Oxidation can be defined with different terms such as: the loss of electrons or hydrogen, or the gain of oxygen by an atom or a molecule.

Overview

Oxidation in Terms of Electron Transfer

Oxidation is the loss of electrons.

For example, in the reaction between iron and copper sulfate solution

copper sulfate and iron sulfate are both ionic compounds. If rewritten as an ionic equation, it turns out that sulfate ions are spectator ions and the reaction can be written as:

where the iron is *oxidized* from metal iron (Fe^0) to ferrous iron (Fe^{2+}) by the loss of two electrons:

while the copper (II) ion, gaining two electrons is reduced to copper metal (Cu^0). Thus, in the reaction, the reductant or ► [reducing agent](#) loses electrons and is oxidized, and the oxidant or *oxidizing agent* gains electrons and is reduced.

Oxidation in Terms of Hydrogen Transfer

Oxidation is the loss of hydrogen.

- Methanol (alcohol) can be oxidized to methanal (aldehyde) by loss of hydrogen

Oxidation in Terms of Oxygen Transfer

Oxidation is the gain of oxygen.

- The reaction between elemental iron and oxygen to form iron oxide involves the oxidation of iron (commonly known as rusting)

In general terms, oxidation implies an increase in an atom's oxidation state. However, it is only correct to speak about the oxidation state of a metal atom when the compound is purely ionic. Molecules, atoms, or ions that have the ability to *reduce* others are said to be reductive and are known as reducing agents, *reductants*, or *reducers*. That is to say, the reductant transfers electrons to another substance, which is, as a result, oxidized. Since, it “donates” electrons it is also called an ► [electron donor](#). The electronic transfer reactions known as redox reactions are especially important in biology because most biochemical reactions imply reduction or oxidation reactions.

Substances that act as reductants include, among others, electropositive elemental metals like lithium, sodium, magnesium, iron, zinc, and aluminum. These metals readily donate or *give away* electrons. *Hydride transfer reagents*, such as NaBH_4 and LiAlH_4 , are widely used in organic chemistry. Another method of reduction involves the use of hydrogen gas (H_2) with a palladium, platinum, or nickel catalyst. These *catalytic reductions* are primarily used in the reduction of carbon-carbon double or triple bonds.

Oxidizing Atmosphere

Franck Selsis
CNRS, Laboratoire d'astrophysique de Bordeaux,
Passac, France

Definition

An oxidizing atmosphere is a (planetary) atmosphere which oxidizes immersed (surface) compounds. It sometimes refers to an O₂-rich atmosphere, for example the atmosphere of modern Earth. Most of the Earth's atmospheric oxygen is generated by biological photosynthesis; however, oxidation can also be an effect of photochemistry initiated by stellar UV radiation. The Martian atmosphere, for instance, is an oxidizing atmosphere. Its main constituents are CO₂, N₂, Ar, and H₂O, but the OH radicals and oxygen atoms produced by photolysis result in surface oxidation and the formation of O₂, O₃ and H₂O₂.

Oxygen Fugacity

Francis Albarède
Laboratoire de Géologie de Lyon, Ecole Normale
Supérieure de Lyon, Lyon Cedex 7, France

Keywords

Mineral redox buffer · Redox reactions ·
Redox zonations

Definition

Oxygen fugacity is an equivalent of the partial pressure of oxygen in a particular environment (atmosphere, rocks, etc.) corrected for the non-ideal character of the gas.

Overview

There are multiple ways of characterizing how reducing or how oxidizing an environment is. An example of a redox reaction in an ideal gas mixture of carbon dioxide, methane, water, and oxygen is:

The status of this reaction can be evaluated by writing the equilibrium equation:

$$\frac{P_{\text{O}_2} P_{\text{CH}_4}}{P_{\text{CO}_2} P_{\text{H}_2\text{O}}^2} = K_1(T) \quad (2)$$

where P_i stands for the partial pressure of gas i and $K_1(T)$ is the reaction coefficient at temperature T . For real gases, pressure P_i should be replaced by fugacities f_i . Fugacity and pressure converge toward each other when the total pressure diminishes.

Likewise, the reduction of magnetite, which contains one Fe^{2+} and two Fe^{3+} , by silica gives fayalite (ferric olivine Fe_2SiO_4), which contains two ferrous ions Fe^{2+} :

For ideal solids and gas:

$$\frac{P_{\text{O}_2} [\text{Fe}_2\text{SiO}_4]}{[\text{Fe}_3\text{O}_4] [\text{SiO}_2]} = K_2(T) \quad (4)$$

where concentrations are in bracket. For pure phases, concentrations are equal to 1, while for real gases P_{O_2} is replaced by f_{O_2} . Taking the logarithm of both sides, we get:

$$\ln f_{\text{O}_2} = \ln K_2(T) = \frac{\Delta H_2}{RT} + \text{Const} \quad (5)$$

where ΔH_2 is the enthalpy of the reaction and R is the gas constant. At a given temperature, the quartz-fayalite-magnetite (QFM) mineral assemblage (see entry ► [“Mantle, Oxidation of”](#)) imposes or “buffers” a particular value of f_{O_2} . For all practical purpose, oxygen fugacity measures the electron trade among minerals and describes the proportions of Fe^{2+} and Fe^{3+} coexisting in the rock, rather the other way around. Under most conditions, the f_{O_2} is so low that oxygen is actually fully combined to the mineral phases and is not present as a gas. Oxygen fugacity is a robust estimate of the redox conditions because rocks are electrical insulators. Other buffers of oxygen fugacity exist, such as iron-wüstite (IW), which describes the coexistence of

metallic iron Fe^0 and Fe^{2+} in extremely reducing environments like the lunar mantle.

Oxygen Isotopes

Ko Hashizume

Faculty of Science, Ibaraki University, Ibaraki, Japan

Keywords

Isotope anomaly · Fractionation mass independent · Organic matter · Photochemistry · Self-shielding · Solar composition · Water

Definition

Oxygen has three stable isotopes: oxygen-16, oxygen-17, and oxygen-18. In most studies on terrestrial samples, only the $^{18}\text{O}/^{16}\text{O}$ ratio is usually measured and discussed, where the mass-dependent fractionation law, expressed by $\delta^{17}\text{O} \approx 0.52 \times \delta^{18}\text{O}$, can be safely assumed (see ► [Delta, Isotopic](#), for the δ notation). The $\delta^{17}\text{O}$ values among extraterrestrial samples significantly deviate from the above shown relationship. This deviation bears prime importance in cosmochemistry and, naturally, in astrobiology.

Overview

Oxygen is the most abundant element in the planetary system, except among the giant planets, Jupiter and Saturn, where hydrogen and helium

dominate their masses. Oxygen is accommodated as a major constituent in most types of building blocks, rocks (MO_x), water (H_2O), and organics (CHONS), which are essential in constructing a terrestrial planet, particularly a habitable planet. Oxygen isotope compositions among solid planetary materials are generally expected to bear keys to understand the history of these building blocks, from their births to their accretion into planets or asteroids, although the details are vigorously debated until now (Fig. 1).

Basic Methodology

The oxygen isotope ratios among samples are normally expressed in the δ -notation, that is, by the difference of the ratios in per mill unit relative to the ratios of the reference standard; $\delta^x\text{O} \equiv (R/R_{\text{std}} - 1) \times 1,000$; $R = {}^x\text{O}/{}^{16}\text{O}$ ($x = 17$ or 8). The international reference standard is the standard mean ocean water (SMOW) with ${}^{17}\text{O}/{}^{16}\text{O}$ and ${}^{18}\text{O}/{}^{16}\text{O}$ ratios of 3.73×10^{-4} and 2.005×10^{-3} , respectively.

Oxygen Isotopes, Fig. 1 The oxygen three-isotope diagram for important end-member compositions that contributed to planetary compositions. The inserted figure displays the O-isotope compositions among the bulk

meteorites. Note that the terrestrial fractionation “line” (TFL) is precisely a curve when plotted over a large range of δ values. Refer to the main text for other notations

Key Research Findings

Classically, it was considered that rocks and water were produced from a hot and homogenous solar gas through equilibrium condensation processes. In this case, we expect that the O-isotope compositions among the raw material and all products, that is, the solar and planetary compositions, respectively, are uniformly plotted on a single line in the $\delta^{17}\text{O}$ versus $\delta^{18}\text{O}$ diagram with a relationship of $\delta^{17}\text{O} \approx 0.52 \times \delta^{18}\text{O}$, namely, the terrestrial fractionation line (TFL). (Readers are advised to refer to the cross-references for further basics on isotope fractionation, particularly on mass-dependent fractionation.) However, in 1973, Clayton and coworkers discovered that O-isotope compositions among carbonaceous chondrites deviate from the TFL but are plotted around a line with a much steeper slope of 0.94, so-called the carbonaceous chondrite anhydrous minerals (CCAM) line. Later works (Young and Russell 1998) demonstrated that the slope is exactly one among the less-altered components in the meteorites, but the slope displayed among assemblages of chondritic minerals actually measured is slightly smaller, because of the contributions from altered components, whose O-isotope compositions are somewhat mass-dependently fractionated from their original compositions. Note that the non-mass-dependent fractionation trend of oxygen is not a peculiar observation among the carbonaceous chondrites but is observed among essentially all available extraterrestrial materials, including meteorites possibly from Mars or from Vesta, one of the largest asteroids (Clayton 1993, 2005).

Many possible explanations have been submitted to explain the origin of the slope 1 trend. It was first explained that the non-mass-dependent O-isotope trend originated from contributions from a hypothetical ^{16}O -rich exotic component, possibly of nucleosynthetic origin (Clayton 1993). However, later measurements of O-isotope compositions among pre-solar oxide grains (Nguyen et al. 2007) suggest that the ^{16}O -rich component is rather rare among the pre-solar grains and thus may not contribute to alter the bulk meteoritic compositions. The alternative explanations

recently supported are the fractionations associated with chemical processes that took place in the early [solar nebula](#) or in the ancestral molecular cloud. The two different chemical processes proposed are mass-independent fractionation (MIF) and the CO self-shielding.

MIF is typically seen in the process that operates in ozone formation in the terrestrial upper atmosphere (Thiemens 1999). Ozone is formed in the pathway as follows: $\text{O} + \text{O}_2 \leftrightarrow \text{O}_3^*$; $\text{O}_3^* (+\text{M}) \rightarrow \text{O}_3$, where O_3^* denotes the vibrationally excited state and M is a third molecule that stabilizes the excited ozone by collision. The origin of MIF is considered to be the lower density of the vibrational quantum states for the symmetric isotopomer (OQO^*) compared to the asymmetric one (QOO^*), where Q is either ^{17}O or ^{18}O . The resident time of QOO^* is longer than OQO^* ; thus QOO is stabilized more efficiently than OQO . The QOO excess may occur for both ^{17}O and ^{18}O , by which the MIF signal is produced. Marcus (2004) proposed that similar reactions such as $\text{O} + \text{XO} \leftrightarrow \text{XO}_2^*$; $\text{XO}_2^* (+\text{M}) \rightarrow \text{XO}_2$ ($\text{X} = \text{Si}, \text{Ca}, \text{Al}, \text{etc.}$), involving MIF, might have occurred in the early solar nebula, during the formation of calcium-aluminum-rich inclusions, which are particularly enriched in ^{16}O , plotted on the CCAM line.

The CO self-shielding is proposed to take place during the photodissociation of CO in a gas medium that consists of H_2 and CO, irradiated by external radiation fields (van Dishoeck and Black 1988; Visser et al. 2009). At a wavelength of 91–108 nm, CO shows narrow and isotopically separated absorption bands leading to its photodissociation through the [predissociation](#) mechanism. In a gas medium irradiated by ultraviolet light, the wavelengths which correspond to the absorption bands for $^{12}\text{C} \ ^{16}\text{O}$, the dominant major isotopologue of CO, are more quickly attenuated than those for other minor isotopologues. The CO self-shielding is considered to be responsible for the carbon and oxygen isotope fractionations in molecular clouds (Visser et al. 2009). Many workers attempted to apply the self-shielding effect to the early solar nebula. First, Kitamura and Shimizu (1983) proposed that $^{17,18}\text{O}$ -rich O atoms derived from the self-

shielding effect in the photodissociation of O_2 , exchanged with mineral grains upon shock heating, may lead to $^{17,18}O$ -enriched planetary solid materials. However, Navon and Wasserburg (1985) pointed out that the $^{17,18}O$ -enrichment produced by the self-shielding will be rapidly erased by the reaction between the O atom and O_2 . Clayton (2002) proposed that CO self-shielding may occur at the inner edge of the solar nebula, in the proximity of the Sun. Later models assume that the CO self-shielding occurred at the cold environment, at the envelope of the outer solar nebula (Lyons and Young 2005), or in the parental molecular cloud, part of which later evolved to the solar nebula (Yurimoto and Kuramoto 2004). In these CO self-shielding models, the $^{17,18}O$ -rich isotope signature produced by the self-shielding is assumed to be transmitted to H_2O and finally trapped by the silicate minerals.

We may test these O-isotope fractionation models by the knowledge of several important end-member components. The most important one is the solar composition. The solar composition here refers to the composition of the solar gas at the surface of the Sun. The temperature at the solar surface is low enough to prevent occurrence of any nuclear reactions to alter the O-isotope composition. Also, the mixing of masses between the surface and the solar core is considered to be negligibly small. Therefore, the composition of the gas at the solar surface is considered to preserve the proto-solar composition, representing the bulk composition of the solar nebula. The MIF models assume that the solar O-isotope composition is the same as the terrestrial composition, whereas the CO self-shielding models assume an ^{16}O -rich solar composition. The solar isotope composition can be assessed the most accurately by direct measurement of the solar wind. The surface of the Moon is exposed to the solar wind for up to billions of years. Hashizume and Chaussidon (2005) discovered at the surface of several metallic grains contained in lunar soil samples, irradiated by the solar wind since 1–2 Gyr ago, an oxygen component enriched in ^{16}O by $>2\%$ relative to the terrestrial composition. They assigned the observed ^{16}O -rich oxygen to the solar-wind composition, concluding that the

bulk solar nebula was ^{16}O -rich. However, the situation was complicated by the finding of a distinct O-isotope composition at the surface of metallic grains from a different lunar soil sample, where O was enriched in $^{17,18}O$ by $\sim 3\%$ relative to the terrestrial composition (Ireland et al. 2006). This debate was finally brought to an end by the final result for the O-isotope determination of the solar-wind component captured by the Genesis space mission (McKeegan et al. 2011). The space probe circled the Sun for several years to accumulate solar wind on several substrates, which were returned to Earth in 2004. They estimated the solar composition to be enriched in ^{16}O by $\sim 3\%$ relative to the terrestrial composition ($\Delta^{17}O = \delta^{17}O - 0.52 \cdot \delta^{18}O = -28.4 \pm 1.8\%$). The origin of the $^{17,18}O$ -rich composition observed in some lunar samples is yet unresolved. However, it is tempting to speculate that it represents the oxygen composition of comets that accreted to the Moon, since water ice and organics, the major constituents of comets, could be enriched in $^{17,18}O$ (see below).

The other important end-member compositions, which may serve as tests for several models, are the primordial compositions of water ice and organic matter. The models by Yurimoto and Kuramoto (2004) or Lyons and Young (2005) predict that water ice is the carrier of the $^{17,18}O$ -rich isotope signature, connecting the $^{17,18}O$ -rich O atoms, first produced by the CO self-shielding in the gas medium, and the rocky materials at the midplane of the solar nebula, which finally trapped the isotope signature. Sakamoto et al. (2007) discovered in a primitive carbonaceous chondrite Acfer094, a poorly characterized iron-oxide mineral with O-isotope compositions as high as $\delta^{17}O \approx \delta^{18}O \approx 180\%$. They explained that the iron-oxide mineral was produced by reactions between primordial water and the metallic Fe-Ni or iron sulfides and argued that their observation demonstrates the role of water ice as a carrier of the O-isotope signature produced by the CO self-shielding. Hashizume et al. (2011) discovered that an Antarctic carbonaceous chondrite contains pieces of organic particles that display striking enrichments in ^{17}O and ^{18}O at almost parallel degrees, by as high as 530% relative to the terrestrial composition. The oxygen isotope anomalies were associated with carbon

isotope anomalies, roughly with a relationship of $\delta^{17}\text{O} \approx 1.05 \times \delta^{18}\text{O} \approx 0.5 \times \delta^{13}\text{C}$. By the CO self-shielding, the enrichment of ^{13}C is indeed expected to be associated with the $^{17,18}\text{O}$ enrichment. However, the ^{13}C -rich signature produced among the photodissociated products is considered to be compromised by a competing reaction. The ion molecule reaction ($^{12}\text{CO} + ^{13}\text{C}^+ \leftrightarrow ^{12}\text{C}^+ + ^{13}\text{CO} + 35 \text{ K}$) is particularly active at low temperatures, whose isotope effect is considered to exceed the effect by the self-shielding below a gas temperature of 60 K (Visser et al. 2009). The positive correlation between the $\delta^{17,18}\text{O}$ and $\delta^{13}\text{C}$ observed among the organics suggests that the temperature where the CO photodissociation occurred was higher than the one for the typical molecular cloud core (~10 K), which is the place proposed by Yurimoto and Kuramoto (2004) where the CO self-shielding might have occurred. Hashizume et al. (2011) argued that the organic formation associated with the $^{17,18}\text{O}$ -enrichment probably occurred at the envelope of the solar nebula, a slightly warm (>40 K) and dense gas medium intensively illuminated by the proto-Sun.

Future Directions

The non-mass-dependent O-isotope anomaly, broadly observed among solid planetary materials, was originally considered to represent the origins or formation processes of a subset of the rocky planetary materials. However, recent studies suggest that the O-isotope anomaly is deeply connected to the origins of the low-temperature condensates, that is, the volatiles, represented by the water ice and the organic matter, which are critically important materials in astrobiology. It is important to summarize the two advantages of O-isotopes over other light element (H, C, and N) stable isotopes as a tracer. (1) Oxygen has three isotopes. We may accurately discriminate the original mass-independent isotope signature from the mass-dependent fractionations that may occur by miscellaneous effects. (2) Oxygen is the major constituent in both low- and high-temperature condensates. The oxygen isotope ratios may become one of the most important

tools to trace the entire history of the important ingredients for a habitable planet: from their origins, their distribution processes in the solar nebula, accretion to planets/asteroids, and the processes within the planets, namely, the rock-water-organics interactions, possibly including the life-formation process.

Oxygen Minimum Zone

Daniele L. Pinti

Geotop, Research Centre for the Dynamics of the Earth System, Université du Québec à Montréal, Montréal, QC, Canada

Keywords

Anoxia · Archean ocean · Anaerobia · Denitrification · Hypoxia · Nitrogen cycle · Oxygenation of the Earth · Redox zonation

Acronyms

OMZ Oxygen-minimum zone

Synonyms

Dead zone; Shadow zone

Definition

The oxygen-minimum zone or OMZ is the zone in a body of water or depth in a water column in which the oxygen saturation is minimum and thus redox conditions are hypoxic (O_2 concentration $<75 \mu\text{mol/L}$) or anoxic (O_2 concentration $<1 \mu\text{mol/L}$).

Overview

In terrestrial oceans, the oxygen-minimum zone develops between 200 and 1000 m below the sea level. The development of the OMZ in oceans is mainly related to the consumption of oxygen by aerobic bacteria degrading dead organisms descending through the water column from the above-oxygenated ocean layer. At depths >1000 m, the ocean is again oxygenated because the bottom currents bring cold, oxygen-rich, polar waters. On the continental platform, sediments in contact with the OMZ are also in anoxic conditions, allowing the preservation of buried organic matter.

OMZ plays a key role in regulating the ecological community structure of the global ocean. In this zone, important metabolic activities take place regulating the cycle of several life-related elements, such as nitrogen. Indeed, in this poor-oxygen zone, organisms must develop peculiar strategies to survive, as denitrifiers, heterotrophic anaerobic bacteria which are able to consume oxygen from nitrates, through denitrification at very low O_2 level of a few μM (Sigman et al. 2009; Ulloa et al. 2012); or anammox bacteria which convert nitrite and ammonium ions directly into diatomic nitrogen by anaerobic ammonium oxidation at oxygen concentrations up to about $10\text{--}20 \mu\text{M}$ (Ulloa et al. 2012). Both metabolic processes transform nitrates and nitrites back into N_2 , completing the atmosphere-hydrosphere global nitrogen cycle (Sigman et al. 2009). Several astrobiology teams study the OMZ at

different climatic conditions in terrestrial lakes and oceans because it might represent the best analogue of the Archean anoxic oceans or those in the early Proterozoic when only the upper superficial layer was oxygenated. Studying the prokaryote communities living in the OMZ can give important clues on the evolution of specific organisms and the development of specific catabolic/metabolic activities enabling survival in a quasi-anoxic environment.

Oxygen minimum zones may have developed in oceans located on the icy moons of our Solar system. Europa is thought to host a subsurface ocean with substantial amounts of O₂ sourced from ice radiolysis. Pending the rate at which Europa's ice shell is mixed with the ocean, as well as the rates at which this O₂ is consumed, it may accumulate to concentrations comparable or even higher than those in Earth's oceanic oxygen minimum zones (Hand et al. 2009; Ward et al. 2019).

Definition

Oxygen is a chemical element with atomic number 8, represented by the symbol O. The name *oxygen* was coined in 1777 by Lavoisier. It derives from the Greek word “oxys” meaning “sharp,” referring to the sharp taste of acids, and “genēs” meaning “producer.” It is a chalcogen and is highly reactive, forming compounds such as oxides with most other elements. Oxygen is also the name of the molecular compound O₂, also known as ► [dioxygen](#), formed from two covalently linked oxygen atoms with a spin triplet electron configuration.

Oxygen is the third most abundant element in the universe by mass, after hydrogen and helium, and the most abundant element by mass in the Earth's crust. Dioxygen as a gas makes up 20.9% of the volume of Earth's atmosphere and is also present in the form of water vapor and CO₂. Oxygen makes up 49.2% of the Earth's crust by mass, mostly in the form of silicates, carbonates, and metal oxides, and is the major component of seawater at 88.8% by mass, in the form of water.

All major classes of biological molecules, including proteins, nucleic acids, carbohydrates, and fats, contain oxygen, as do the major inorganic compounds that comprise animal shells, teeth, and bone. Oxygen was independently discovered by Scheele in 1773 (or possibly earlier) and Priestley in 1774.

Naturally occurring terrestrial oxygen includes three stable isotopes: ^{16}O , ^{17}O , and ^{18}O . ^{16}O is the most abundant, making up 99.762% of the natural abundance. Most ^{16}O is synthesized at the end of the helium fusion process in stars, but some is made by neon burning. ^{17}O is primarily produced by the burning of hydrogen into helium during the CNO cycle. ^{18}O is produced when ^{14}N captures a ^4He nucleus during stellar fusion.

Due to its electronegativity, oxygen forms chemical bonds with almost all other elements to give corresponding oxides. The ► [oxidation](#) state of atomic oxygen is -2 in almost all known oxygen-containing compounds, but in a few compounds such as peroxides, the oxidation state is -1 .

Definition

Oxygenases catalyze the transference of oxygen from molecular oxygen to an oxidized substrate. They are a group of ► [enzymes](#) that form a class of oxydoreductases (enzymes that catalyze the transference of electrons from one molecule (called reductant) to another (the oxidant)). There are two classes of oxygenases: mono-oxygenases, which transfer an oxygen atom from molecular oxygen to the substrate and reduce the other atom to water, and dioxygenases, which are able to transfer both oxygen atoms to the substrate.

Oxygenation of the Earth's Atmosphere

David C. Catling
Department of Earth and Space Sciences,
University of Washington, Seattle, WA, USA

Keywords

Rise of oxygen · Oxygenation

Synonyms

[Atmospheric redox change](#); [Earth's oxygenation](#)

Definition

Earth's oxygenation is an increase in the concentration of atmospheric molecular oxygen (O_2) from levels of less than 1 ppmv before 2.45 Ga to 21% by volume today. Larger amounts of atmospheric oxygen became possible because of shifts in the competition between the production of oxygen derived from ► [photosynthesis](#) and the rate of consumption of oxygen by different geological processes. Evidence from ancient rocks suggests that oxygenation happened in steps, with a first rise of O_2 at 2.45–2.32 Ga and a second around 0.75–0.58 Ga. The latter increase was a precursor to the appearance of macroscopic animals.

Overview

The present atmosphere contains (by volume) 78.05% N_2 , 20.95% O_2 , 0.93% Ar, 0.038% CO_2 , and various trace gases. With the exception of argon, the concentrations of all of the major gases are biologically modulated. Oxygen, in particular, is almost solely biogenic because it has no

significant abiotic source. Consequently, before life existed, the atmospheric partial pressure of O_2 is estimated to have been $<10^{-13}$ bars. The importance of O_2 cannot be overstated: without sufficient O_2 , the Earth would have no large multicellular plants, no land animals, and no humans or consciousness. A particular type of photosynthesis, ► [oxygenic photosynthesis](#), is responsible for supplying O_2 to the atmosphere. Jan Ingenhousz, a Dutch physician and botanist, discovered oxygenic photosynthesis in 1779, by showing that when green plants are exposed to sunlight they produce oxygen. In the nineteenth century, many single-celled photosynthesizers were identified in addition to plants, which included algae and organisms that were initially called *blue-green algae*. Like other algae, the blue-green ones were assumed to have the same cellular structure as plant cells, as a matter of definition. However, in the 1970s, blue-green algae were recognized as bacteria and were reclassified as ► [cyanobacteria](#) through the efforts of Roger Stanier, a Canadian microbiologist. Our modern description of oxygenic photosynthesis is a process by which green plants, algae, and cyanobacteria split molecules of water into hydrogen and oxygen. The hydrogen is used inside cells to chemically reduce carbon

dioxide to organic matter, while the oxygen is released as O_2 waste gas.

In the twentieth century, geochemistry uncovered the history of Earth's atmospheric O_2 levels, showing that for roughly the first half of Earth history, up until about 2.4 Ga, O_2 concentrations were less than 1 ppmv (parts per million by volume) (Fig. 1). The first person to describe evidence that O_2 levels were significantly different on the early Earth was the geologist Alexander MacGregor. In the 1920s, MacGregor examined Archean (pre-2.5 Ga) sedimentary rocks in modern-day Zimbabwe and deduced that they formed in an atmosphere devoid of O_2 because they lacked the reddish-colored, oxidized iron minerals that are ubiquitous in analogous modern sediments. MacGregor's conclusion greatly influenced Preston Cloud, an American geologist, who further investigated the geologic record for information on past atmospheric O_2 . Cloud also championed a suggestion originally made in 1959 by the marine biologist John Nursall that the relatively late appearance of macroscopic fossils animals in the geologic record reflected the slowness in reaching a sufficiently O_2 -rich atmosphere.

Modern geochemical research shows that an initial transition to an oxygenated atmosphere

Oxygenation of the Earth's Atmosphere,

Fig. 1 A schematic history of atmospheric oxygen according to geologic constraints discussed in the text

occurred in the period 2.45–2.32 Ga, but the O₂ levels attained were probably only 0.1–2% by volume and apparently insufficient for supporting macroscopic animals. This first “rise of oxygen” is also called the ► *Great Oxidation Event* (GOE). Although much less than today’s 21% by volume, the post-GOE O₂ levels were enough to dominate the redox chemistry of the atmosphere. Such O₂ levels were also ample for producing a stratospheric ozone (O₃) layer, which ever since has protected life on the Earth’s surface from biologically harmful ultraviolet radiation. The first fossils visible to the naked eye occur after the GOE at 1.87 Ga and are thought to represent a seaweed, *Grypania spiralis*. In a second increase in O₂, over the period 750–580 Ma, O₂ rose to levels of at least tens of percents of modern times, that is, a concentration between 2% and present levels. The first animal fossils appear in the Ediacaran Period (635–542 Ma), with the oldest soft-bodied fossils of Ediacaran Biota at ~575–565 Ma. While there is a consensus that sufficient O₂ was a necessary physiological precursor to animal life, there remains considerable debate among paleontologists about whether an increase in O₂ caused large animals to appear or whether other evolutionary and ecological factors were crucial.

Explaining why O₂ increased is more elusive than it might first appear. We might suppose that when cyanobacteria evolved, O₂ would have accumulated in the atmosphere. But the consensus interpretation of geochemical evidence (discussed below) is that cyanobacteria produced O₂ for several hundred million years or more before 2.4 Ga, while atmospheric O₂ levels remained <1 ppmv. A pertinent consideration is that the Earth’s overall chemical composition is reducing, so that reactions of O₂ with geothermal gases in the atmosphere or certain cations in the ocean (e.g.,

Fe²⁺) in an initially reducing environment must have acted as a powerful chemical buffer opposing the accumulation of atmospheric O₂. Consequently, we need to carefully consider the losses of O₂ as well as its source for understanding past changes in O₂ levels. In this regard, the modern oxygen cycle helps to elucidate some of the basic concepts of source and sink fluxes before discussing how sources and sinks were probably different on the ancient Earth.

The O₂ Balance Sheet: Gains and Losses

The theoretical subtleties of how photosynthesis can influence long-term atmospheric O₂ levels were not fully appreciated until the 1970s, in spite of the fact that a French geologist, Jacques Ebelmen, correctly described the key ideas in 1845. Ebelmen implicitly realized that photosynthesis is nearly a zero-sum activity. Oxygenic photosynthesis can be summarized by the following schematic equation:

where “CH₂O” represents the average stoichiometry of organic matter. Oxygen consumption by respiration or decay of organic matter reverses Eq. 1, and produces no net oxygen on timescales greater than about 10² years. Oxygen only escapes respiration or oxidative decay on geologic timescales because a tiny fraction (0.1–0.2%) of organic carbon is buried, mainly in marine sediments, which segregates the oxygen from the organic matter. Some organic matter is also used in biogeochemical processes to make ► *pyrite* (FeS₂) from seawater sulfate ions (SO₄²⁻(aq)) as follows:

Consequently, pyrite burial also liberates oxygen into the atmosphere or ocean. Remarkably, Ebelmen correctly identified both organic carbon burial and pyrite burial as the long-term sources of atmospheric oxygen. Unfortunately, his ideas went unnoticed and the same concepts had to be reinvented.

While it is useful to think of the burial of organic carbon and pyrite as a “net source” of O_2 , it is important to appreciate that this “net” O_2 is lost to numerous other sinks for O_2 besides the reversal of Eq. 1. The geological sinks and sources of O_2 are shown in Fig. 2. By reviewing the average composition of new sediments, American geochemist Heinrich Holland has estimated that burial fluxes of organic carbon and pyrite produce oxygen at rates of 10.0 ± 3.3 and 4.7 ± 1.2 Tmol O_2 year⁻¹, respectively, where 1 Tmol = 10^{12} mol (Holland 2002). The reduction of oxidized iron from its +3 oxidation state to the +2 state ($2Fe_2O_3 = 4FeO + O_2$) and subsequent burial also adds a minor flux of O_2 , whereas the burial of sulfate minerals in sediments removes O_2 . Summing these burial fluxes, the total O_2 net source is 15.6 ± 4.0 Tmol O_2 year⁻¹ (Table 1). Dividing the current amount of oxygen in the atmosphere–ocean reservoir (3.78×10^{19} mol O_2) by the source flux (1.6×10^{13} mol O_2 year⁻¹)

gives ~ 2.4 Ma for the average amount of time an O_2 molecule spends in today's atmosphere–ocean system. Consequently, over such timescales, the net source of O_2 must be closely balanced by losses or O_2 levels would wildly fluctuate. We know that centimeter- to meter-sized animals, which require O_2 to grow and breathe, have been continuously present in the Phanerozoic eon (542 Ma to present) so that concentrations of atmospheric O_2 must have been within 0.2 ± 0.1 bar. The O_2 source is balanced by O_2 losses that include reactions in the ocean with dissolved minerals and gases from hot seafloor vents, and reactions of O_2 dissolved in rainwater with continental minerals, principally those containing elemental carbon, sulfide, and ferrous iron (Fig. 1). Gases that consume O_2 in the atmosphere or ocean are CH_4 , H_2 , CO , SO_2 , and H_2S . These are released either from hot rocks that melt (volcanism) or hot rocks that do not melt (metamorphism). Estimates of their fluxes are shown in Table 2. The O_2 sink from submarine and subaerial volcanic gases is ~ 2.3 Tmol O_2 year⁻¹, metamorphic gases consumes ~ 3.1 Tmol O_2 year⁻¹, and subduction of oxidized seafloor causes a loss of ~ 0.2 Tmol O_2 year⁻¹. The sink due to continental weathering is 12.0 ± 3.3 O_2 year⁻¹, which is estimated from the

Oxygenation of the Earth's Atmosphere, Fig. 2 Schematic diagram of source and sink fluxes of oxygen on geologic timescales

composition of average rock undergoing weathering (Table 2). Thus, within the large ~25% uncertainty of the data, the source flux of O₂ from organic carbon and pyrite burial of 15.6 ± 4.0 Tmol O₂ year⁻¹ is matched by the total sink flux of 17.7 ± 4.5 Tmol O₂ year⁻¹. In the past, changes in the relative proportions of source and sink fluxes evidently caused O₂ levels to change.

Oxygenation of the Earth’s Atmosphere, Table 1 Modern source fluxes of O₂ (Holland 2002). The pyrite flux corrects for an error in Holland (2002)

Oxygen fluxes	× 10 ¹² mol O ₂ year ⁻¹	Effect on O ₂
Organic carbon burial flux	10.0 ± 3.3	Production
Pyrite (FeS ₂) burial flux	4.7 ± 1.2	Production
Sulfate burial flux	−(0.3 ± 0.1)	(Loss)
Reduced iron burial flux	0.9 ± 0.4	Production
Total rate of oxygen production ~ (15.6 ± 4.0) × 10 ¹² mol O ₂ year ⁻¹ (taking sulfate as redox neutral)		

Evidence for Earth’s Oxygenation

The Great Oxidation Event at 2.45–2.32 Ga occurred in the Paleoproterozoic era (2.5–1.6 Ga), the first of three eras within the Proterozoic eon (2.5–0.542 Ga), which follows the Archean eon (before 2.5 Ga). After the Paleoproterozoic, the Mesoproterozoic (1.6–1.0 Ga) and the Neoproterozoic (1.0 Ga–542 Ma) eras follow. The second rise of O₂ (750–580 Ma) occurred in the Neoproterozoic. We can tell that O₂ levels changed by studying at the chemistry of rocks from these eras. The Great Oxidation Event (GOE) produced binary geochemical changes in the Paleoproterozoic because the atmosphere changed the oxidation states (from weakly reducing to oxidizing), whereas the Neoproterozoic changes are subtler because an oxic atmosphere merely became more oxygenated. Let us consider evidence for the GOE and Neoproterozoic increase of O₂ in turn.

Evidence for the Great Oxidation Event (GOE)

The different oxidation state of continental minerals that were formed before and after the GOE

Oxygenation of the Earth’s Atmosphere, Table 2 Modern sink fluxes of O₂ (Holland 2002; Catling and Kasting 2016)

Type of flux	× 10 ¹² mol O ₂ year ⁻¹	Effect

Fe ²⁺ conversion to magnetite and Fe ²⁺ release	~0.4 ± 0.2	(Loss)
Total rate of oxygen loss ~ (17.7 ± 4.5) × 10 ¹² mol O ₂ year ⁻¹		

records a change from an atmosphere essentially devoid of O_2 to one redox dominated by O_2 . The presence or absence of O_2 changes the chemistry of minerals that are formed because O_2 dissolves in rainwater and reacts with minerals. Three continental indicators are red beds, paleosols, and detrital grains (Holland 1984). ► *Red beds* are riverbanks, deserts, and floodplains with a reddish pigmentation that arises when an iron oxide coating on mineral grains is produced from the rusting of iron minerals. Before the GOE, no red beds are found in the geologic record, indicating a lack of O_2 , whereas afterward red beds are common. ► *Paleosols* are lithified soils. Before the GOE, paleosols show a loss of iron, which is consistent with leaching by ancient anoxic rainwater, whereas after ~ 2.2 Ga, iron is not leached. Iron will be flushed through a soil in the form of soluble ferrous iron ions (Fe^{2+}) if rainwater has little dissolved O_2 but if the air contains $>0.2\%$ O_2 , iron will be oxidized into insoluble and immobile oxides such as ► *hematite* (Fe_2O_3). Cerium is another redox-sensitive element that has also been examined in paleosols. Cerium oxidizes from Ce^{3+} to Ce^{4+} to form cerianite (CeO_2), so the presence of Ce^{3+} -rich minerals in paleosols from the Archean implies an early anoxic atmosphere. *Detrital grains* in sediments are those that are never completely dissolved during the process of weathering. Rounded detrital grains from sediments deposited by turbulent Archean rivers commonly contain minerals that would only survive at very low levels of O_2 . Detrital grains of pyrite (FeS_2), ► *uraninite* (UO_2), and siderite ($FeCO_3$) place bounds on the concentration of Archean O_2 of roughly $<2\%$, $<0.2\%$, and $<0.02\%$, respectively, compared to today's 21% O_2 . In modern oxygenated waters, uraninite dissolves to form soluble U^{6+} ions, pyrite oxidizes to soluble sulfate (SO_4^{2-}) and hematite, and siderite rusts to produce insoluble hematite.

The chemistry of seawater also changed after the GOE, with increased levels of sulfate and much decreased levels of redox-sensitive elements such as manganese and iron that are insoluble when oxidized. Marine sulfur isotopes are the data that indicate an increase in sulfate concentrations. Today, sulfate-reducing bacteria

produce most of the sulfide in marine sediments. These bacteria reduce $^{32}SO_4^{2-}$ in preference to $^{34}SO_4^{2-}$ so that bacterial sulfide is enriched in ^{32}S . However, this fractionation ceases in waters with <0.2 mM sulfate concentration. Archean sulfides have $^{34}S/^{32}S$ ratios close to an unfractionated mantle value, implying Archean oceans with <0.2 mM sulfate, compared to 28.9 mM in today's surface seawater. Rivers ultimately supply sulfate to the ocean by washing sulfate off the land where it is produced by the oxidation of sulfides by oxygenated rainwater. Consequently, the low concentration of seawater sulfate before the GOE is consistent with low atmospheric O_2 . By 2.3–2.2 Ga, sulfides with significant ^{34}S depletions formed ubiquitously in the ocean, reflecting increased sulfate and the rise of O_2 . When O_2 rose, it also oxidized and titrated manganese out of the ocean, producing the world's largest manganese deposit found in the 2.2 Ga Hotazel Formation in South Africa. The presence of ► *banded iron formations* (BIFs) provides evidence that the deep ocean was devoid of O_2 in the Archean, unlike today. By definition, BIFs are laminated marine sedimentary rocks containing ≥ 15 wt% iron, with alternating iron-rich and iron-poor layers. The iron mainly originated from hydrothermal sources in the deep ocean, such as ► *mid-ocean ridges*. Today, iron is oxidized in the deep ocean and deposited on the flanks of the ridges. But in the anoxic depths of Archean oceans, ferrous iron was transported to the continental shelves where it was (microbially) oxidized and precipitated as iron minerals in the BIFs. In the Paleoproterozoic, BIFs decline in abundance and disappear after ~ 1.8 Ga. Chromium (Cr) isotopes in the BIFs also record changes in atmospheric O_2 . When insoluble Cr^{3+} is oxidized to soluble Cr^{6+} during oxidative weathering, the heavy isotope ^{53}Cr is preferentially oxidized relative to ^{52}Cr . After transport from rivers to the ocean, the Cr isotopic fractionation is preserved in ocean sediments. An increase in the abundance of ^{53}Cr after 2.4 Ga compared to Archean samples further confirms the GOE.

The strongest evidence for the GOE is a large amount of mass-independent fractionation (MIF)

of ► **sulfur isotopes** in sedimentary rocks older than 2.45 Ga compared to little or no sulfur isotope MIF in rocks younger than 2.32 Ga. In modern rocks, ^{32}S , ^{33}S , and ^{34}S obey “mass-dependent” fractionation, in which the difference in abundance between ^{33}S and ^{32}S is approximately half that between ^{34}S and ^{32}S , that is, a linear relationship with mass difference. Most processes, such as microbial sulfate reduction, produce mass-dependent isotope fractionation. In contrast, mass-independent fractionation in sulfur isotopes is where the relative abundance of different isotopes deviates from linear, mass-dependent fractionation. Laboratory studies show that large MIF is produced exclusively from photochemical reactions, such as the photolysis of SO_2 . Three conditions are needed for the production and preservation of the sulfur isotope MIF: O_2 levels below about 1 ppmv, sufficient sulfur gas in the atmosphere, and relatively large concentrations of reducing gases. In a high- O_2 atm, sulfur gases are rapidly oxidized and rained out as dissolved sulfate. But in the absence of O_2 and in the presence of reducing gases such as 10^2 – 10^3 ppmv methane, sulfur exits the atmosphere as sulfide, elemental sulfur, or sulfate, which allows the mass-independent fractionation produced by anoxic photochemistry to be segregated and preserved in different sedimentary minerals. In summary, the sulfur isotope MIF provides evidence for an Archean atmosphere with both low O_2 and high methane.

Donald Canfield (of the University of Southern Denmark) has proposed that a significant fraction of the deep ocean remained sulfidic rather than oxygenated during much of the Proterozoic, after 1.8 Ga (Canfield 2005; Lyons et al. 2009). In this model, BIFs declined because increased sulfate in the surface ocean caused sulfate-reducing bacteria to provide a flux of sulfide to the deep ocean, which scavenged ferrous iron into insoluble iron sulfides. This is an alternative to a model where the disappearance of BIFs at 1.8 Ga is explained by the oxygenation of the deep ocean and the formation of insoluble iron oxides (Holland 2006). In today's ocean, <0.5% of the seafloor is *euxinic*, meaning oxygen free with

H_2S . Molybdenum (Mo) isotopes are useful indicators of oxygenation and euxinia because oxic uptake of Mo on marine solids preferentially removes ^{95}Mo relative to ^{98}Mo , leaving the ocean isotopically heavy. In contrast, in times of low oxygenation, marine Mo is isotopically light. In highly euxinic deep waters, Mo is scavenged efficiently and tends to capture the Mo isotope composition of seawater. Rocks that are ^{95}Mo -enriched from the 1.7 to 1.4 Ga MacArthur Basin in Australia suggest that the deep ocean in the mid-Proterozoic seafloor was commonly oxygen-poor, with a greater proportion of euxinia than today. The data suggest that the euxinia was probably only several percent of the ocean's area, but this is enough to have had a significant effect in depleting trace metals in the Mesoproterozoic Ocean, which may have impacted marine ecology for a billion years until the Neoproterozoic.

Evidence for a Neoproterozoic “Second Rise” in Oxygen

Sulfur and chromium isotopes in marine sediments indicate that O_2 increased in the late Neoproterozoic. At this time, marine sedimentary sulfides occur with ^{32}S -enrichment exceeding the isotope discrimination of sulfate-reducing bacteria. The interpretation is that isotopically light sulfide was re-oxidized at the sediment-water interface and cyclically re-reduced by sulfur-disproportionating bacteria, which increased the isotope fractionation. The greater sulfur isotope fractionation is therefore related to oxygenation of the near-shore seafloor. Canfield (2005) has estimated that the oxygenation required atmospheric O_2 concentrations in excess of 1–4%. A large increase in the abundance of marine ^{53}Cr relative to ^{52}Cr after 750 Ma also confirms an increase in atmospheric O_2 . Oxygen would have mobilized greater amounts of chromium during continental oxidative weathering, which is the mechanism of isotopic fractionation mentioned earlier. Fossil evidence for animals greater than a few millimeters or more in size also suggests that O_2 concentrations exceeded 2%, which is the minimum level that can support aerobic metabolism in such animals via O_2 supplied by diffusion.

When Did Oxygenic Photosynthesis Evolve?

In order to understand the early history of atmospheric O₂, we need to examine the evidence for the advent of oxygenic photosynthesis. In particular, the geologic record suggests that oxygenic photosynthesis arose 300 Ma or more before the GOE. This timing is inferred from a variety of proxies including biomarkers, nonmarine stromatolites, redox-sensitive metals, and sulfur isotopes, which we discuss in turn.

Biomarkers are recognizable derivatives of biological molecules, which are usually in the form of certain hydrocarbons found in kerogen (noncrystalline sedimentary organic matter) or oil. Chemical changes induced when sediments convert into rock strip biological molecules of functional groups but can often leave a distinctive molecular backbone, in a way that is analogous to the more familiar macroscopic process that removes flesh to leave fossilized skeletons that we can associate with particular life forms. Biomarkers from the Archean have been the subject of controversy because of the possibility of contamination from modern molecules or fluid migration over geologic time and uncertainties regarding their specificity for particular organisms and metabolisms. Recent advances in ultra-clean drilling and the ability to analyze oil-bearing fluid inclusions help to address concerns about contamination. Biomarkers for cyanobacteria are 2- α -methylhopanes, which are derived from compounds in cell membranes. Long chain varieties of these particular molecules (i.e., >C₃₁) occur very rarely outside the cyanobacteria. In addition, steranes derive from sterols, which are found in the membranes of eukaryotes and synthesized in a pathway that requires free molecular oxygen. For example, 11 molecules of O₂ are required to produce one molecule of cholesterol. No bacteria are known to synthesize C₂₆-C₃₀ sterols and archaea do not synthesize sterols at all. The simultaneous co-detection of long chain (>C₃₁) 2- α -methylhopanes with eukaryotic sterols is thus a reasonable biosignature for oxygenic photosynthesis. Such a combination of biomarkers has been found in fluid inclusions in the 2.45 Ga Matinenda Formation at Elliot Lake, Canada,

which consists of sandstones deposited prior to the GOE (Dutkiewicz et al. 2006). However, measurements of biomarkers from 2.72 to 2.56 Ga rocks in the Hamersley Province of northwest Australia (Eigenbrode et al. 2008) and 2.67–2.46 Ga rocks from the Transvaal of South Africa (Waldbauer et al. 2009) are now in doubt because recent work suggests that Archean biomarkers are contaminants (French et al. 2015).

► **Stromatolites** (laminated rocks formed by microbes) from a 2.72 Ga lake in the ► **Tumbiana Formation** in northwest Australia possibly confirm the presence of O₂ production. Geologic evidence shows that the lake lacked sulfate and hydrothermal reductants needed for non-oxygen-producing photosynthesis. Consequently, a process of elimination suggests that microbial communities using oxygenic photosynthesis may have constructed these particular stromatolites (Sakurai et al. 2005).

Furthermore, the mobility of redox-sensitive metals indicates the presence of some O₂ before the GOE, and therefore the presence of oxygenic photosynthesis. Molybdenum (Mo), rhenium (Re), and chromium (Cr) are soluble only when oxidized. Consequently, a spike in Mo and Re concentrations found in 2.5 Ga sedimentary rocks in the Hamersley district of northwest Australia suggests that a transient “whiff” of O₂ occurred in the atmosphere about 100 Ma prior to the GOE (Anbar et al. 2007). The whiff is confirmed by contemporaneous evidence of sulfur isotopic fractionation indicating a spike of sulfate. Enrichments of ⁵³Cr relative to ⁵²Cr (which are induced by oxidative weathering) are also found in banded iron formations at low levels for at least 300 Ma prior to the GOE, which is consistent with the biological production of O₂ (Frei et al. 2009). In summary, multiple lines of evidence suggest that oxygenic photosynthesis existed at least 0.3 billion years before the GOE.

Theories for Oxygenation

At present, a framework has been developed for understanding why the GOE occurred, but the cause of the second rise of O₂ in the Neoproterozoic remains very obscure (Catling and Claire 2005).

The GOE happened because either O_2 production increased or O_2 consumption declined. The ancient, pre-2.45 Ga oceans were largely devoid of sulfate, so that organic carbon burial dominated O_2 production prior to the GOE, while pyrite burial was unimportant. Consequently, it has been argued that O_2 rose because the rate of organic carbon burial (O_2 production) increased, either as a pulse or long-term trend. One suggestion is that the growth of early continental shelves promoted organic carbon burial and oxygen production. But there are grounds for skepticism about this proposal. Organic matter extracts the light carbon isotope, ^{12}C , from seawater, but marine carbon, recorded in ancient limestone, does not significantly decrease in ^{12}C content between mid-Archean and Mesoproterozoic rocks. Notably, at 2.3–2.1 Ga, many marine carbonates are unusually depleted in ^{12}C relative to ^{13}C , which could be explained if there was a large pulse of burial of organic carbon, but then the ^{12}C content returns to its previous value. A burial pulse would merely generate a parallel pulse of O_2 , given the short residence time of O_2 and not a persistently increased level of O_2 . Instead, the pulse was more plausibly an effect of increased O_2 because the Paleoproterozoic excursions in the ^{12}C of limestones follow the rise of O_2 before 2.32 Ga.

A widely accepted explanation for why little atmospheric O_2 accumulated in the Archean is that a large flux of volatile and aqueous reductants, that is, chemicals that consume oxygen, scavenged the O_2 . In time, the geological sources of reductants declined to the point where the O_2 flux produced from organic carbon burial exceeded the kinetically rapid consumption flux. At this tipping point, oxygen flooded the atmosphere until O_2 levels reached a new plateau where continental weathering became the predominant balance for O_2 production. Various suggestions have been made for why the proportion of reductants in volcanic or metamorphic outgassing might diminish and cause such a tipping point. One suggestion is that a change in the style of outgassing from submarine to subaerial volcanism favored a decline in the proportion of reductants. Another consideration is that an

anoxic atmosphere would always allow a relatively high concentration of hydrogen-bearing reducing gases. At high altitude, the decomposition of such gases causes hydrogen to escape to space at a rate that is significant on geologic timescales, which oxidizes the whole Earth and diminishes further release of reductants. In particular, in an anoxic atmosphere, methane reaches concentrations hundreds of times greater than today's 1.8 ppmv. Most methane is ultimately produced microbially from fermentation of photosynthesized organic matter. Ultraviolet light decomposes methane in the upper atmosphere, causing it to lose hydrogen. When hydrogen escapes from the planet, oxygen is gained irreversibly through a schematic reaction as follows:

Evidence for this hypothesis is found in the redox components of the crust. If photosynthesis were the only process responsible for segregating redox components, the number of moles of equivalent O_2 in the Earth's crust should be balanced by equimolar reduced carbon (Eq. 1). But instead there is excess oxygen in the crust by a factor of 1.5–2.2 (Catling and Claire 2005; Sleep 2005). The excess can be quantitatively reconciled with time-integrated hydrogen escape and net oxidation expected from a methane-rich Archean atmosphere.

Various geological and biological causes have been suggested for the Neoproterozoic second rise of oxygen, but the problem remains unsolved. Geological proposals include the enhanced production of clays that adsorbed and buried organic matter, or the assembly of a supercontinent whose weathering added nutrients to the sea and stimulated organic carbon burial. Also, it has been suggested that moderately high levels of methane throughout the Proterozoic could have promoted hydrogen escape and oxidized the Earth. Biological proposals include continental weathering accelerated by lichen, and the evolution of zooplankton with fecal pellets that enhanced organic

burial. However, presently, all of these ideas for the cause of the second rise of O_2 are, at best, just qualitative proposals.

Conclusion and Future Directions

The atmosphere evolved from an anoxic to oxygenated state. There are multiple lines of geochemical evidence for a rise of O_2 or *Great Oxidation Event* (GOE) at 2.45–2.32 Ga. However, oxygenic photosynthesis appears to have existed at least 0.3 billion years beforehand. A self-consistent explanation for the delay between the origin of oxygenic photosynthesis and oxygenation of the atmosphere is that excess volatile reductants efficiently scavenged O_2 . This sink on O_2 diminished until the GOE occurred. Following the GOE, sulfate levels increased in the ocean as a result of a greater role for oxidative weathering in balancing O_2 production from the burial of organic carbon and pyrite. In the late Precambrian, around 750–580 Ma, a second rise of O_2 occurred, along with a further increase in marine sulfate. This second rise appears to have been a precursor to the appearance of macroscopic animals.

Considerable further research will no doubt further constrain the levels of O_2 through geologic time and our understanding of the past biogeochemical cycles of various elements – such as carbon, sulfur, and nitrogen. Measurements of new isotopic systems, such as those of trace metals, will no doubt bring advances. ► [Bio-markers](#) also have the potential to reveal what microorganisms and microbial processes were present in the Precambrian biosphere. But currently, Archean biomarkers are plagued by the issue of contamination (French et al. 2015).

Photosystem I · RuBisCO

Definition

Photosynthesis is the biological process of converting the energy in visible light into chemical energy available for the cell to fix CO₂ into biomass for growth. Oxygenic photosynthesis is a unique version of photosynthesis that uses water as the electron donor, producing dioxygen as a product.

Chemical Formula

Acronyms

3-PGA	3-Phosphoglycerate
ATP	Adenosine triphosphate
CIII	Complex III
Fd	Ferredoxin

GOE	Great Oxygenation Event
NADPH	Nicotinamide adenine dinucleotide phosphate
PC	Plastocyanin
PSI	Photosystem I
PSII	Photosystem II
Q	Quinol/quinone
RuBisCO	Ribulose 1,5-bisphosphate carboxylase oxygenase
RuBP	Ribulose 1,5-bisphosphate
WOC/ OEC	Water-oxidizing complex/Oxygen-evolving complex

Overview

Oxygenic photosynthesis is fundamental to life as we know it today. This metabolism accounts for the vast majority of primary productivity on Earth and maintains our atmosphere rich in O₂ and far from chemical equilibrium with the solid Earth, thus representing a presumptive biosignature on a planetary scale. It is carried out by members of the bacterial phylum *Cyanobacteria* and the constitutively related chloroplasts of algae and plants, with major global contributions from both terrestrial and marine ecosystems.

Oxygenic photosynthesis evolved once, roughly 2.4 billion years ago, in the *Cyanobacteria* and was a key turning point in the history of life on Earth. Unlocking the ability to use the abundant resource of H₂O as an electron donor for photosynthesis allowed for a massive increase in primary productivity and expansion of the biosphere, while the production of O₂ transformed Earth surface environments and led to the evolution of aerobic biochemistries – the latter, by extension, enabled complex multicellular life.

Mechanics

To capture sunlight, photosynthetic organisms use pigment molecules like the tetrapyrrole chlorophyll to absorb light energy, generating an excited state of the pigment molecule. This excited state migrates from pigments in light-harvesting antenna systems to the reaction center – a protein complex with a pair of pigments that utilizes the excitation energy of the chlorophyll to engender charge separation and electron transfer. When the chlorophyll pair (P) is promoted to the excited state (P^*), it moves an electron to an acceptor molecule, simultaneously generating a strong oxidant (P^+) and a strong reductant (A^-) in different parts of the reaction center. The oxidizing power of P^+ is used to pull electrons from an electron donor, and the reducing power of A^- is sent down the electron transport chain – along its path contributing to the transmembrane potential and thereby ATP synthesis and eventually the generation of low-potential reducing power for CO_2 fixation in the form of NADPH (Fig. 1).

To span the vast amount of redox space between H_2O and NADPH, oxygenic photosynthesis uses two distinct reaction centers coupled in series – photosystem II (PSII), which oxidizes H_2O to O_2 and donates electrons to the quinol pool, and photosystem I (PSI), which takes electrons that have run through complex III from plastocyanin and donates them to a ferredoxin – which can be used at the start of the process to fix carbon. Part of what makes oxygenic photosynthesis special is the ability to derive electrons from water. The key catalyst that enables this is a Mn_4CaO_5 cluster known as the water-oxidizing complex (WOC) or oxygen-evolving complex (OEC), ligated by the PSII complex. The Mn atoms in this cluster cycle through a range of oxidation states, acting as a redox capacitor to bridge the single-electron process of photochemical electron transfer with the four-electron process of oxidizing H_2O to O_2 .

The carbon fixation pathway used in oxygenic photosynthesis to convert CO_2 to sugars for various cellular processes is the Calvin cycle, also known as the Calvin-Benson-Bassham cycle or the reductive pentose phosphate cycle. This cycle consumes the reducing power and ATP

generated as a part of the photochemical reactions involving the electron transport chain that begins at PSII. The Calvin cycle involves numerous biochemical reactions, but can be summarized as three phases – carboxylation, reduction, and regeneration. In carboxylation, the enzyme RuBisCO – the most abundant protein on the planet – adds a CO_2 molecule to ribulose 1,5-bisphosphate (RuBP), a 5-carbon sugar, to generate two molecules of 3-phosphoglycerate (PGA), a 3-carbon sugar. In reduction, PGA is phosphorylated and reduced to produce glyceraldehyde-3-phosphate (GAP), consuming ATP and NADH. Finally, in regeneration, five molecules of GAP are used to regenerate three molecules of RuBP. Thus, for every three molecules of CO_2 that get fixed, six molecules of GAP are produced, five of which are used to regenerate RuBP, with one remaining GAP exported to other metabolic pathways.

Evolution

Anoxygenic photosynthesis is biochemically simpler than oxygenic photosynthesis; it uses single photochemical reaction centers – rather than the coupled photosystems of oxygenic photosynthesis – and electron donors with much lower reduction potentials rather than H_2O . Anoxygenic phototrophy evolved very early in Earth history; geological data suggest this occurred likely prior to 3.4 billion years ago. Today, anoxygenic phototrophy is known to exist in the bacterial phyla *Proteobacteria*, *Chloroflexi*, *Chlorobi*, *Acidobacteria*, *Firmicutes*, *Gemmatimonadetes*, and the candidate phylum WPS-2, and is known to use electron donors such as H_2 , Fe(II), sulfide, and other reduced sulfur species, nitrite, arsenite, and organic compounds. However, none of these phyla appear to be ancestrally phototrophic, leaving the identity of the lineage that invented anoxygenic phototrophy an enduring evolutionary mystery. It is possible that this lineage is now extinct.

There is debate about the evolutionary timing of oxygenic photosynthesis, but a wide array of geological observations indicate that it had evolved from an anoxygenic ancestor in the *Cyanobacteria* by 2.4 billion years ago. This

Oxygenic Photosynthesis, Fig. 1 (a) Schematic diagram of the oxygenic photosynthesis electron transport chain. (b) The Z-scheme, depicting the energetics of electron transfer in oxygenic photosynthesis. Electron flow from a lower-potential electron donor to a higher-potential electron acceptor is thermodynamically favorable. The input of light energy to induce charge separation in the special pair (P680 in the case of PSII, P700 in the case of

PSI) generates a very high-potential electron acceptor (P^+) and a very low-potential electron donor (A^-), allowing for favorable electron flow along the electron transport chain. (c) The Calvin cycle, simplified as three stages – carboxylation, reduction, and regeneration. This pathway uses ATP and NADPH generated by the light-dependent reactions shown in panel A. The enzyme RuBisCO catalyzes the key step of CO_2 fixation

transition involved the evolution of a reaction center with a much higher reduction potential, the innovation of the WOC/OEC to bridge the single-electron photochemistry of the reaction center with the requisite four-electron chemistry for H_2O oxidation, and the coupling of two separate reaction centers in series in the electron transport chain. With the advent of oxygenic photosynthesis came the first meaningful environmental fluxes of O_2 ; this transformed Earth surface environments dramatically and irreversibly, impacted all global biogeochemical cycles, and

redirected the evolutionary trajectory of life by enabling aerobic metabolisms. This defining moment in Earth history is known as the Great Oxygenation Event (GOE).

All photosynthetic eukaryotes (algae and plants) derived their photosynthetic machinery from *Cyanobacteria*, as their chloroplasts originated by the endosymbiosis of a *Cyanobacterium* with a eukaryotic host cell. The earliest algal fossils date to 1.05 billion years ago, while the first land plants emerged circa 488 million years ago.

Ozone

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

Ozone, O₃, is an important trace constituent of the ► [stratosphere](#), where it forms the ► [ozone layer](#). It consists of three atoms of oxygen arranged as an open triangle. Ozone is produced in the three-body reaction $O + O_2 + M = O_3 + M$, where M represents a stabilizing molecule (N₂ or O₂) and O is produced by the photochemical dissociation of O₂. Some other components (NO, Cl, CFCs) catalyze the reaction of ozone destruction $O_3 + O = 2O_2$. The importance of ozone for life preservation lies in its unique capability to block solar UV radiation in a range particularly harmful to organic macromolecules (230–290 nm). It is also a greenhouse gas.

Ozone Layer

Gerda Horneck

DLR German Aerospace Center, Institute of Aerospace Medicine, Radiation Biology, Köln, Germany

Keywords

Oxygen photochemistry · Ozone · UV screening

Synonyms

Stratospheric ozone

Definition

The ► **ozone** layer refers to the ozone within the stratosphere of the Earth, where over 90% of the Earth's ozone resides. This layer absorbs the Sun's high-energy ultraviolet radiation of wavelengths <290 nm. The concentration of ozone is measured in Dobson units (DU).

History

The existence of an ozone layer in the upper regions of our atmosphere was detected in 1913 by Charles Fabry and Henri Buisson. In 1924, G.M.B. Dobson built the first spectrograph to measure the seasonal variation of ozone. From 1928 to 1958, Dobson established a worldwide network of ozone monitoring stations that are operating up to date. In his honor the "Dobson unit" was defined as measure of the columnar density of ozone above the Earth surface (see definition below).

Overview

On Earth, the stratospheric ozone layer is found at an altitude from 20 to 40 km. It is created when ultraviolet radiation from the Sun strikes the oxygen molecules in the stratosphere. By this photochemical process oxygen molecules (O_2) are dissociated to atomic oxygen (O). The atomic oxygen quickly combines with further oxygen molecules to form ozone (O_3). Ozone can be split again into molecular oxygen (O_2) and atomic oxygen under the influence of short wavelength ultraviolet radiation from the Sun (Fig. 1). This continuing process is called ozone-oxygen cycle.

The concentration of ozone in the stratosphere is measured in Dobson units (DU) – named after

Ozone Layer, Fig. 1 Absorption cross-section of ozone as a function of wavelength

Gordon M.B. Dobson, who built the first instrument for measuring total ozone from the ground. It measures the total amount of ozone present in a vertical column of air above a certain location at the surface of the Earth. It is defined in terms of the equivalent millimeter thickness of ozone at an atmospheric pressure of 1013 hPa and a temperature of 298 K: 1 mm of ozone is equivalent to 100 DU. Concentrations of ozone in the stratosphere vary naturally according to temperature, weather, latitude, and altitude. Furthermore, aerosols and other particles ejected by natural events such as volcanic eruptions can have measurable impacts on ozone levels. Near the tropics, values typically reach about 260 DU; these values increase toward the poles.

The stratospheric ozone layer is very effective at screening out solar UV radiation at wavelengths <290 nm. As a result, most of the biologically harmful part of the solar UV radiation does not reach the surface of the Earth. Surface UVB radiation levels are highly variable because of sun angle, cloud cover, and also because of local effects including pollutants and surface reflections. Decreasing ozone concentrations result in higher irradiances of the energetic part (UVB) of the solar spectrum with possible biological

consequences (Häder 1997). The Antarctic ozone hole is an area of the Antarctic stratosphere wherein the total ozone amount is less than 220 DU. It occurs during the Antarctic spring, from September to early December, when over 50% of the lower stratospheric ozone is destroyed. Over the past two decades, the ozone hole has steadily grown in size (up to an area of 27 million km²) and length of existence (from August through early December).

In the Archean (3.8–2.5 billion years ago), the Earth's atmosphere was essentially anoxic and therefore it probably lacked a protective ozone column. Thus, UVB (280–315 nm) and UVC (200–280 nm) radiation could have penetrated to the Earth's surface with their associated biological effects. Using data obtained from the UV-inactivation of *Bacillus subtilis* spores in a space experiment, it has been shown that without the UV screen by stratospheric ozone the biologically effective UV doses would be about 1000 times higher than today (Horneck et al. 1996; Cockell and Horneck 2001). Most of the damage would have been caused by UVC radiation on DNA, which is the decisive target for inactivation and mutation induction at this UV range.

Mars has no planetary ozone layer, although regional small concentrations of ozone may occur

during northern winter periods. As a result, most of the Martian surface is reached by the high energetic solar UV radiation of wavelengths >200 nm.

P

P-P Chains

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

The p-p chain is the series of nuclear reactions converting four protons to one ${}^4\text{He}$ nucleus and releasing an energy of about 6.6 MeV/nucleon or 5×10^{18} erg/gr. This provides the main source of energy for Main sequence [► stars](#) of less than 1.3 M. while in more massive stars the [► CNO cycle](#) dominates. The first reaction of the series ($p + p \rightarrow D + e^+ + \nu_e + 0.42 \text{ MeV}$) involves a slow, weak interaction (the conversion of a proton into a neutron), which is responsible for the long lifetimes (>10 Gyr) of the Sun and other low mass stars.

Synonyms

[Pentopyranosyl-RNA](#); [Pyranosyl-RNA](#); [Ribopyranosyl nucleic acid](#)

Definition

Pyranosyl-RNA (“p-RNA”) is an [► oligonucleotide](#) in which the ribose units exist in the pyranose form and are linked together repetitively by phosphodiester groups between the hydroxyl groups at positions C-2' and C-4' (Fig. 1).

p-RNA, Fig. 1 A constitutional and an idealized conformational representation of pyranosyl-RNA (p-RNA); base = adenine, guanine, cytosine, uracil, thymine, as well as 2,4-diaminopurine, xanthine, iso-guanine, and iso-cytosine

History

The systematic experimental study of nucleic acid alternatives has played an important role in understanding the chemical etiology of the structure of nucleic acids as functioning biomolecules (Eschenmoser 1993b). In 1992, Eschenmoser conceived the structure of p-RNA in context of the study toward the chemical etiology of the natural nucleic acid structure (Eschenmoser 1993a). The existence of p-RNA was predicted through a comprehensive and systematic qualitative conformational analysis of all possible hexo- and pentopyranosyl oligonucleotide systems that could be derived from the products of the aldol reaction of glycolaldehyde phosphate with itself and with formaldehyde (Pitsch et al. 1994).

Overview

Pyranosyl-RNA is a constitutional ► **isomer** of RNA, composed of the very same building blocks as natural RNA. p-RNA contains the D-ribose building unit in the pyranosyl (six-membered ring) form with the phosphodiester bonds linking the C(4') atom of one pyranosyl unit with the C(2') atom of the neighboring pyranosyl unit. Among the four possible pentopyranosyl (ribo-, arabino-, lyxo-, and xylo-) oligonucleotides, ribo-pyranosyl nucleic acid (p-RNA) has been studied

extensively with respect to its base-pairing properties, structure, and function (Pitsch et al. 1993, 1995; Eschenmoser 1993b, 1997, 1999, 2011; Krishnamurthy et al. 1996; Schlönvogt et al. 1996; Micura et al. 1997; Bolli et al. 1997a, b; Beier et al. 1999; Jungmann et al. 1999; Pitsch et al. 2003).

p-RNA oligomers form duplexes that are more selective (Watson-Crick mode, antiparallel orientation of strands) and stronger than the corresponding natural (furanosyl) RNA and DNA oligomers; the Hoogsteen or reverse Hoogsteen pairing modes seem not to be accessible (Pitsch et al. 1995; Eschenmoser 1993b, 1997). Watson-Crick purine-pyrimidine base-pairing in p-RNA is highly enantioselective; p-RNA duplexes comprised of strands of identical chirality were observed to be the strongest among the various possible combinations (Krishnamurthy et al. 1996). In spite of having a less flexible pyranose-unit containing backbone, p-RNA is capable of adopting secondary structures with similar ease as RNA, such as hairpin structures, containing three bases in the loop (Micura et al. 1997).

The overall base-pairing and nonenzymatic replicative properties of p-RNA (and other hexo- and pentopyranosyl-NA) have been discussed in the context of nature's choice of RNA (DNA) as the molecular basis for a genetic system (Beier et al. 1999; Eschenmoser 1999). Two primary conclusions drawn from these studies are that

(a) Watson-Crick base-pairing mode is not unique and specific to the double helix type of conformation characteristic of a ribofuranose system, but is widespread among potentially natural alternatives derived from the structural neighborhood of RNA, and (b) the selection of RNA (and DNA) seems not to be based on the criterion of maximizing base-pairing strength; rather, RNA and DNA seem to have optimal pairing capabilities with respect to achieving turnover in strand replication.

Basic Methodology

The basic methodology underlying the identification and investigation of p-RNA consisted of four parts:

- (1) Identification of p-RNA: a qualitative conformational analysis of repetitive base-pairing arrangements of the four possible pentopyranosyl-NAs led to the selection of p-RNA as a candidate to be synthesized and further investigated.
- (2) Synthesis of p-RNA: the required nucleoside building blocks of p-RNA were generated by synthetic organic chemistry, such as the reaction of a protected ribose with nucleobases by *Vorbrüggen* or *Hilbert-Johnson* nucleosidation, followed by synthetic manipulations to generate the phosphoramidites. The corresponding oligonucleotides were synthesized on a gene synthesizer using the phosphoramidites (automated solid-phase oligonucleotide synthesis) and isolated by ► [HPLC](#) techniques.
- (3) Investigation of the physical and chemical properties of p-RNA: the base-pairing and structural properties were investigated by UV, CD, and NMR spectroscopy.
- (4) Evaluation of the properties of p-RNA: the relevant base-pairing and structural properties of p-RNA were compared with those of natural RNA and DNA. The comparison of these properties and the capacity to replicate by (nonenzymatic) template-directed ligation were used to reason out why ribopyranose nucleic acid is probably not a biological functioning molecule in extant biology.

Key Research Findings

NMR investigations revealed that the p-RNA-(**CGAATTCG**) duplex adopts a quasi-linear (ladderlike) structure with a weak left-handed twist (Schlönvogt et al. 1996). There is a large inclination of the backbone relative to the base-pair axes. Such a marked inclination of the backbone/base-pair-axes has a profound effect on the base-pairing properties of p-RNA such as (a) the highly sequence-dependent thermal stabilities, (b) the stronger and more selective base-pair formation, (c) the duplex stabilizing effect of the 2'-end dangling base, and (d) alternate or block sequences containing pyrimidine-purine arrangements forming more stable duplexes than the inverse series.

Remarkably, p-RNA undergoes extensive cross-pairing with oligonucleotides derived from the three other members of the (4'→2')-pentopyranosyl family; extensive intersystem cross-pairing among the members was observed, in spite of the differences in the stereo-centers of the (4'→2')-phosphodiester-linked oligonucleotides (Jungmann et al. 1999). However, no duplex formation was observed between the pentopyranosyl-derived oligonucleotides with RNA or DNA.

The distinctive chemical properties of p-RNA confer it with certain functional advantages when compared to the natural RNA and DNA oligomeric systems. For example, investigations of the (nonenzymatic) template-directed ligation of p-RNA sequences (via the 2',3'-cyclophosphate activation) have demonstrated this process to be (a) very efficient (due to the absence of purine-purine self-pairing in Hoogsteen or reverse Hoogsteen mode), (b) highly regioselective (forming only the desired 4'→2' linkage over the undesired 4'→3', due to the large backbone/base-pair inclination. In contrast, the corresponding template-directed ligation of RNA forms exclusively the unnatural 5'→2' linkage over the natural 5'→3') (Bolli et al. 1997b), and (c) highly chiroselective (replacement of D-ribopyranosyl with L-ribopyranosyl nucleoside unit hampers the ligation reaction) (Bolli et al. 1997a, b). Hairpin-forming p-RNA sequences also act as

templates for mediating the ligation reaction. However, product inhibition (as a consequence of high base-pairing strength) has impeded any prospects for catalytic “turnover.” On the other hand, such strong base-pairing strength facilitates cooperative co-oligomerization of short hemi-self-complementary tetrameric sequences (activated as the 2',3'-cyclophosphate) resulting in an efficient self-templating oligomerization process that leads to the formation of duplexes of higher oligomers (demonstrated up to 24-mers) starting from homochiral 4-mers (Pitsch et al. 2003).

Applications

In the field of biosensor technologies and molecular diagnostics, there have been a lot of efforts devoted toward developing methods for the detection and identification of target biological agents, e.g., nucleic acids. Typical methods for the analysis of DNA amplification products by PCR involve ► [hybridization](#) assays, such as DNA microarray, real-time PCR, and flow cytometry. p-RNA has been utilized for the development of methods and devices for immobilizing and detecting nucleic acid amplicons. Amplicons are comprised of a forward primer conjugated to a synthetic binding unit and a reverse primer conjugated to a detectable moiety that can hybridize to a complementary strand. This complementary strand serves as a synthetic capture unit localized at a predetermined location on the surface of the substrate. By binding the synthetic capture unit with the synthetic binding unit, the amplicon becomes immobilized under sufficient conditions, producing a complex in which the detectable moiety of the amplicon complex indicates the presence of the target nucleic acid in the sample. p-RNA can be incorporated into the synthetic binding and capture units due to its strong, selective, and reversible pairing properties (Huang et al. 2010).

DNA sequencing has also been useful for understanding the function of genes in human or other organisms and for applying many of the basic techniques of molecular biology by the

control of genes. p-RNA molecules can be used as nucleic acid probes in sequencing by hybridization. The probes comprise predefined patterns of universal nucleotides (nucleic acid analogues including p-RNA) and designate nucleotides (canonical nucleic acids), the so-called gapped probes. In the process of sequencing, gapped probes allow each probe to operate in more than one way, requiring a smaller number of probes than conventional probes composed entirely of natural nucleic acids. By the inclusion of p-RNA in the probes, efficient and rapid sequencing of longer nucleotide sequences can be realized compared to sequencing using traditional probes (Preparata et al. 2003).

Future Directions

p-RNA and other biomolecules, such as a peptides, proteins, or nucleic acids, conjugated through a covalent linkage may function as a sequence recognition unit since the conjugates contain two pairing systems which are orthogonal to one another. Specifically, coupling of the first oligonucleotide analog with the second oligonucleotide analog such as p-RNA may form anti-sense molecules capable of binding specifically to a target sequence of polynucleotides and also capable of activating a nuclease or catalyzing cleavage of the target polynucleotides.

Additionally, the inherent properties of p-RNA make it suitable for use in the field of nanotechnology, such as the production of novel supramolecular materials. For instance, p-RNA which contains a non-hydrogen-bonding tryptamine self-pair forms new supramolecular system exhibiting comparable stability to the natural pair due to strong interstrand stacking in the p-RNA duplex (Hamon et al. 1999). This model pairing system can be derivatized with a fluorescent probe without the necessity of additional labeling.

PAH Hypothesis

Marco d'Ischia and Paola Manini
Department of Chemical Sciences, University of
Napoli Federico II, Naples, Italy

Keywords

Polycyclic aromatic hydrocarbons (PAHs) ·
Unidentified infrared emission · Nitrogen-
containing PAHs · Mixed aromatic-aliphatic
organic nanoparticles (MAONS)

Definition

The Polycyclic Aromatic Hydrocarbon (PAH) hypothesis states that the infrared spectra of many galactic and extragalactic objects, dominated by emission features at 3.3, 6.2, 7.7, 8.6, and 11.2 μm , are due to the infrared (IR) fluorescence of PAHs upon absorption of ultraviolet (UV) photons. Despite early criticisms based on the lack of a good match between authentic PAH spectra and the astronomical spectra, most of the weaknesses of the original PAH hypothesis have been addressed. In the currently accepted version, the refined PAH hypothesis includes, besides pure PAHs, mixtures of PAH-related species, PAH clusters, cations, grandPAHs, and nitrogen-containing PAHs (Peeters 2011).

Overview

The PAH hypothesis (not to be confused with the PAH world hypothesis, Platts 2004) links the main carriers of UIE bands to PAH compounds and complex mixtures of related species supposed to be present in both galactic and extragalactic environments (Allamandola et al. 1989, Cook and Saykally 1998). UIE bands refer to infrared emissions from circumstellar regions, interstellar media, star-forming regions, and extragalactic objects, which have remained for a long time unassigned since their original discovery. The main features of UIE occur around 3.3, 6.2, 7.7, 8.6, 11.2, and 12.7 μm , but include also weak emissions within the $\sim 5\text{--}18$ μm range. Following several observations correlating UIE bands with carbon compounds, in the mid-1980s independent papers by Leger and Puget (1984) and Allamandola (1985) concurred to suggest that the main carriers of the UIE bands were PAHs.

Basic Methodology

Evidence supporting the PAH hypothesis includes:

1. The banded (rather than continuous) nature of the spectrum and the close association of this emission with UV radiation, suggesting that emission is due to gas phase molecules excited by a single UV or visible photon rather than thermal emission from a solid material (Blasberger et al. 2017, Lopez-Puertas et al. 2013).
2. The correlation between the fraction of the total infrared energy that is emitted from planetary nebulae through these features and the amount of available carbon.
3. The correlation between the features of varying emission bands, suggesting that a single class of chemical species is responsible for these spectral signatures.

The assignments supporting the PAH hypothesis can be summarized as follows:

- 3.3 μm band assigned to C-H stretching mode
- 6.2 μm band assigned to C-C stretching mode
- 7.7 μm band assigned to coupled C-C stretching and C-H in-plane bending modes
- 8.6 μm band assigned to C-H in-plane bending mode
- Bands in the 10-15 μm region assigned to C-H out-of-plane bending modes.

Key Research Findings

Beyond the PAH Hypothesis

Although the pillars of the PAH hypothesis were generally accepted, several issues were raised over the subsequent two decades which questioned the validity of assumptions based on pure PAHs as the sole actual carriers of UIE bands (Peeters 2011). Main arguments that were reported include: (1) poor match between experimental and/or theoretical PAH spectra and the astronomical spectra; (2) marked variability in band profiles for interstellar vs circumstellar emissions; (3) the position of the 6.2 μm band cannot be reproduced by the strongest C-C stretching of pure PAHs, indicating that pure PAHs alone cannot account for spectral data.

The possibility that the IR emission spectra could be better matched by structurally modified

PAHs rather than by pure PAHs then gained increasing credit and received a good deal of attention. Accordingly, several modification processes leading to diverse PAH-related species were considered to account for UIE bands, including:

- (a) heteroatom substitution and particularly inclusion of nitrogen in the PAH scaffold to give polycyclic aromatic nitrogenated hydrocarbons (PANHs) (e.g., Peeters et al. 2002, Bauschlicher et al. 2009) like those supposed to be present in Titan's tholins and including conjugated imine and nitrile functionalities;
- (b) aggregation to form PAH clusters such as dimers and trimers (Rapacioli et al. 2005, Simon and Joblin 2009);
- (c) ionization to give random mixtures of PAH cations (Rosenberg et al. 2014).
- (d) reduction to hydrogenated derivatives (Hammonds et al. 2009).
- (e) PAH-metal complexes (e.g., Hudgins and Allamandola 2005, Bauschlicher and Ricca 2009, Simon and Joblin 2010, Joalland et al. 2009) in which a metal atom is located either below or above the carbon skeleton;
- (f) post-synthetic induction of nonplanar structural defects in aromatic core molecular structures (π domains) confined in disordered carbon mixed-phase aggregates (Galué and Díaz Leines 2017);
- (g) variations in the size distribution of the PAH family (Bauschlicher et al. 2008, Bauschlicher et al. 2009, Cami 2011);
- (h) UV processing of the aliphatic components of carbonaceous objects leading to variable proportions of aliphatic versus aromatic moieties (Sloan et al. 2007, Acke et al. 2010).

The grandPAH Hypothesis

Andrews et al. (2015) analyzed the PAH emission at different photodissociation regions and found that the emission features in the 5–15 μm range would lend support to the concept of grandPAHs, previously defined as a set of the most stable PAH species that can survive in the harsh conditions of the interstellar medium (Tielens 2013). The concept of grandPAHs

relies on some main points including: a) the spectroscopic similarity between the three observed spectra even in the smallest details; b) the insensitivity of the PAH emission to the shape of the radiation field. Subtle variations in the abundance distribution of the preferred set of PAHs can explain the observed minor variations between the observed spectra.

PANHs

Parker et al. (2015) emphasized the possible importance of aromatic structures with embedded nitrogen atoms (nitrogen-substituted polycyclic aromatic hydrocarbons, PANHs) in the organic pool of prebiotic relevance in meteorites. PANHs attracted interest since the discovery of vitamin B3 (niacin) and pyrimidines and purines in carbonaceous chondrites like Murchison (Schmitt-Kopplin et al. 2010) suggesting an extraterrestrial origin. The discovery that dihydro(iso)quinolines and potentially more complex PANH-type scaffolds can be produced via facile low temperature reaction channels involving pyridyl radicals with 1,3-butadiene in ultra-low temperature environments provided a more solid background to implicate PANHs in the gas phase of the interstellar medium. In particular, the formation of van der Waals complexes between conjugated molecules with double or triple bonds and an attacking aromatic radical, which lowers the initial reaction barrier to a virtually barrierless addition route leading to a resonance stabilized free radical intermediate, paves the way to an incredibly rich chemistry in the realm of aromatic nitrogen compounds which may parallel that involved in PAH formation and processing. The inclusion of nitrogen into aromatic scaffolds network does not affect the chemistry to any significant degree due to isoelectronicity of nitrogen to methyldiyne (CH) groups. This implies that the reaction routes leading to mass growth and PAH formation are open to nitrogen-bearing systems as well. It is relevant in this connection that PANH derivatives were detected in tholins, a model system for Titan's haze (Sagan et al. 1992), supporting a more relevant astrochemical role of nitrogenated heterocyclic PAHs than so far believed (Landra and Mebel 2010).

Mixed Aromatic-aliphatic Organic Nanoparticles (MAONs)

The central tenet of the PAH hypothesis ascribing the UIE features to purely aromatic carriers was further challenged by studies highlighting the importance of discrete and broad aliphatic spectral features pointing to amorphous organic solids with a mixed aromatic-aliphatic structure, or mixed aromatic-aliphatic organic nanoparticles (MAONs) (Kwok and Zhang 2011). The MAON-based interpretation of spectral data relies also on the marked analogy of this putative carrier with the kerogen-like insoluble organic matter (IOM) in carbonaceous chondrites. The apparent structural and physico-chemical similarity between chondritic IOM and circumstellar dust would shed light on the possible stellar origin of Solar System organics. Moreover, taking as a working hypothesis the formation of MAONs from mixtures of cosmic gases would entail that UIE carrier conceivably features, besides a structural complexity, also a varied chemical composition to include, in addition to carbon and hydrogen, such elements as oxygen, nitrogen, and sulfur. Functional groups bearing O, N, and S may be revealed by analyses at higher spectral resolution and may further compound the original structural model underpinning the PAH hypothesis beyond the emerging aliphatic-aromatic paradigm.

Photochemical Processing of PAHs

Given the widespread occurrence of PAHs in astronomically relevant environments, a crucial question is whether and to what extent PAHs may be susceptible to degradation by UV and cosmic radiation. Although they appear to be abundantly present in photon-dominated regions, their IR emission bands are strongly suppressed toward dense clouds, indicating their confinement to cold grains ($T \leq 30$ K) in the form of interstellar ices. Accordingly, the elucidation of the photochemical behavior of PAHs in water ices has been an important goal since the pioneering studies by Allamandola and colleagues (Bernstein et al. 1999, Bernstein et al.

2001) as well as by other groups (Gudipati and Rui 2012). In all cases a broad range of products including mainly hydroxylated and quinone species was observed, purportedly arising from water-mediated oxygenation pathways. Significant erosion processes leading to the release of CO₂ likely via formaldehyde were also detected, indicating a complex interplay of UV-dependent photochemical pathways accounting for the generation in the interstellar space of oxygen-incorporating PAH-related species of possible relevance to IOM formation and generation of life molecules.

Future Directions

Since the mid-1980s the PAH hypothesis, implicating PAHs as the main carriers of UIE bands, has been subjected to continuous revisions and refinements. As a result, to-date this hypothesis has gradually evolved to incorporate a variety of concepts and phenomena that have relegated PAHs from the original role of dominant carriers of IR emission to that of mere precursors or components of very complex and aggregated organic systems including also aliphatic, cationic, and heteroatom-substituted moieties. If viewed from this broader perspective, the PAH hypothesis still retains its validity after 35 years and can provide the fundamental background to trace the pathway from interstellar medium carbon species to complex organic matter like chondritic IOM of possible prebiotic relevance in planetary environments. In this connection, it would be attractive to revisit the old and largely abandoned PAH world hypothesis in terms of a direct involvement in abiogenesis of PAH-based organic species or domains, like those found to be present in chondritic IOM.

Paleomagnetism

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble,
France

Definition

Paleomagnetism is the record of the Earth's past magnetic field preserved in rocks. The orientation of the magnetic field, retained in ferromagnetic minerals (Fe-Ti oxides and sulfides), mirrors the Earth's magnetic field at the time the minerals passed through their Curie point (i.e., the temperature at which certain magnetic materials undergo a sharp change in their magnetic properties). By measuring the orientation (inclination and declination) and the intensity of this magnetism, it is possible to establish the paleo-latitude of the sample at the time of its cooling or recrystallization. Apparent ► [polar wander](#) curves (the shift in the geographical poles relative to Earth's surface) determined using paleomagnetic data record the displacement of continents and provide evidence of past tectonic plate movements. Variations in intensity of the remnant field record changes in the strength of the Earth's magnetic field and the start of crystallization of the inner core. Paleomagnetism has also been measured on Mars and

shown that natural remnant magnetism is concentrated in the southern hemisphere, suggesting a single-hemisphere dynamo generator.

Paleosols

Kosei E. Yamaguchi
Geochemical Laboratory, Department of
Chemistry, Toho University, Funabashi, Chiba,
Japan

Keywords

Atmosphere rock alteration (mechanical and chemical) · Weathering profile

Definition

A paleosol is a layer of lithified ancient ► [“Weathering Profile”](#) or paleoweathering profile (not necessarily a lithified “soil”) that formed in place by alteration of its parent geologic materials by physical, chemical, and in many cases, biological ► [“Weathering”](#) processes. In the astrobiological context, Precambrian paleosols have been targets of in-depth research, and also focus hot debate, in attempts to constrain the chemical composition, particularly the redox state, of the coeval atmosphere. Paleosols, especially their uppermost parts, were in direct contact with the atmosphere during their formation and were affected directly (through atmosphere land exchanges) and indirectly (through percolating rainwater) by its chemistry. However, in many cases, the uppermost parts of paleosols were eroded away (weathered sections are easily removed by physical processes) before deposition of the overlying sedimentary materials.

Overview

General overviews of paleosols are given in Kraus (1999) and Retallack (2001). “Paleosols” are not necessarily fossil “soils”; they are, in a broad sense, paleoweathering profiles to variable degrees. Hereafter, we focus on the astrobiological aspects of paleosols as important materials that potentially record atmospheric evolution in the distant past. Continental weathering and its elemental fluxes into the oceans should have been very different under an oxic atmosphere or under an anoxic atmosphere, because (bio)geochemical behaviors of what we call “redox-sensitive elements,” such as iron, are very different (e.g., Ohmoto 1996; Rye and Holland 1998). (Bio)geochemical reactions that mobilize or stabilize elements in weathering profiles are influenced by (1) the redox state of weathering fluids, which is in turn affected by atmospheric chemistry and (2) development of terrestrial biota as a source of organic acids that would accelerate rock weathering. Because of such potentials, Precambrian paleosols have

been focus of in-depth research, and at the same time, of controversies (e.g., Ohmoto 1996).

The biggest problem is probably to unambiguously identify a complete section of paleosol. Misidentification of a middle (or deeper) part with an uppermost part (because it was eroded away) leads to serious misinterpretation of geochemical data of the profile (e.g., Rye and Holland 1998; Beukes et al. 2002; Yang and Holland 2003; Yamaguchi et al. 2007). Middle or deeper weathering horizons of modern weathering profiles typically show a signature indicating reducing conditions (e.g., leaching of Fe), even when an oxic atmosphere overlies the uppermost part of the paleosol. Therefore, discovering reducing horizons in paleosols developed before the inferred GOE at around 2.4 Ga (e.g., Rye and Holland 1998; Yang and Holland 2003) does not necessarily indicate that the coeval atmosphere was reducing/anoxic.

Paleosols have been used to constrain not only O₂ but also CO₂ or CH₄ concentrations in the ancient atmosphere (e.g., Rye et al. 1995; Sheldon 2006). Rye et al. (1995) proposed that the concentration of CO₂ as a greenhouse gas in the 2.2 Ga old atmosphere was not high enough to sustain warm climate under the faint young sun, and that CH₄, an additional and powerful greenhouse gas, was required. This suggestion indicates that the atmosphere was not oxic, because substantial amounts of CH₄ and O₂ do not usually coexist. Remnants of arguably the oldest terrestrial life have been reported from a 2.6 Ga paleosol in South Africa (Watanabe et al. 2000). More studies with older samples may extend such records further back in time.

Pallas

Carmen Tornow
Institute of Planetary Research, German
Aerospace Center, Berlin, Germany

Definition

(2) Pallas named after Greek goddess Pallas Athena is located in the main asteroid belt between 2.13 AU and 3.41 AU (<http://ssd.jpl.nasa.gov/sbdb.cgi>). Its inclination is higher than the one of the majority of numbered asteroids. Pallas revolves in 4.61 years around the sun and rotates in 7.81 h around itself. With a radiometric diameter of 545 km, it is the second largest asteroid after (1) Ceres. However, due to its lower density (2762 kg/m³) it has only 81% of the mass contained in (4) Vesta. As a B-type asteroid its chemical composition can be related to the one of carbonaceous chondrites subjected to some thermal processing.

History

The discovery of Pallas on March 28, 1802, by astronomer Heinrich W. M. Olbers was a lucky coincidence since it passed Ceres during this time. Olbers tried to verify the positions of Ceres predicted by Carl F. Gauss, 1801. At that time astronomers thought that a planet would orbit between Mars and Jupiter according to the Titus–Bode hypothesis. This conjecture seemed to be confirmed by the detection of Ceres. However, the discovery of Pallas has put serious doubts on this assumption. The point-like appearance of Ceres and Pallas has motivated William Herschel in 1802 to recommend a separate category for these objects called asteroids (<http://dictionary.reference.com/browse/asteroid>), which was finally accepted by the community. However, both notations (asteroid and planet) were used over many decades of years. Continuing his study of asteroid families Kiyotsugu Hirayama 1928 has identified a small set of objects linked with Pallas and sharing its orbital and spectral characteristic parameters within some range of variability. Today, the existence of the Pallas asteroid family with a clearly larger set of members is well accepted.

Pangea

Nicholas Arndt
 Maison des Géosciences, LGCA, Université
 J. Fourier, St-Martin d’Hères, France

Definition

Pangea is the name of the supercontinent that existed through most of the Paleozoic, from about 480 to 180 Ma. It comprised the older portions of all present landmasses. The single enormous ocean surrounding Pangea was accordingly named Panthalassa. The reasons for the formation of the Pangea supercontinent are poorly understood. Around 180 Ma ago, it started to split apart, initially into the supercontinents ► [Laurasia](#) and ► [Gondwana](#), subsequently into the present continents. The ponding of mantle plumes below the pangean continental lithosphere may have weakened it and favored large-scale continental rifting and breakup.

History

In his book *Die Entstehung der Kontinente und Ozeane*, the German astronomer and meteorologist Alfred Wegener postulated that all the

[Interplanetary transfer of life](#)

Definition

Panspermia (Greek: πανσπερμία from $\pi\tilde{\alpha}\zeta/\pi\tilde{\alpha}\nu$ (pas/pan) “all” and σπέρμα (sperma) “seed”) is the hypothesis that “seeds” or “spores” of life can survive space travel and spread throughout the Universe. Consequences of this hypothesis are that life on Earth may have originated at some other place in the Universe and its evolution on Earth is due to a fertilization of the planet through such interplanetary or interstellar transfer of “seeds.” Consequently, life could be delivered to and start a new evolution on all habitable planets, moons, and satellites.

History

The term *Panspermia* is known to have been mentioned in the fifth century BC for the first time by the Greek philosopher Anaxagoras. He might have influenced scientists in the Middle Ages, as, for example, Giordano Bruno (1548–1600). Giordano had access to old Greek scriptures in the libraries of the medieval monasteries and universities and he proposed the existence of multiple worlds. However, he did not propose interplanetary transfer of life between these worlds. The idea of Panspermia was revived in the nineteenth and twentieth centuries by scientists like J. J. Berzelius (1779–1848), W. T. Kelvin (1824–1907), H. von Helmholtz (1821–1894), S. Arrhenius (1859–1927), and F. Hoyle (1915–2001). During that time the main idea originated that if life once started at some place, it may be able to spread to other environments suitable for replication. Some controversial theories even proposed that diseases may originate in space with space-borne viruses causing, for example, influenza (Hoyle and Wickramasinghe 1979, 1986; Hoyle et al. 1984). But according to Henderson et al. (1989) the likelihood of this theory to hold true is very low.

Overview

Panspermia can occur in three different ways. (1) The classical Panspermia hypothesis

postulates the transfer of uncovered “seeds” by radiation pressure through space (Arrhenius 1903, 1908). (2) The so-called Lithopanspermia (Greek: litho = stone) hypothesis assumes that a ► [rock](#) hosts the organisms during interplanetary transfer. Panspermia should not be confused with the hypothesis based on the formation of chemical compounds in interstellar molecular clouds that assumes that the first prebiotic molecules also formed there. The interstellar molecular clouds are formed after the explosions of the first generations of ► [stars](#) in supernovae. This prebiotic complex organic material can be transported by solar or ► [stellar winds](#) into deep space and may have “seeded” a planet that may then be host to the resulting formation and evolution of life. The seeds are assumed to be interstellar dust grains, ► [meteorites](#), and ► [comets](#) (Chyba and Sagan 1992; Martins et al. 2008).

Francis Crick also intriguingly postulated a “directed Panspermia” where intelligent beings would be deliberately “seeding” the Universe (Crick and Orgel 1973). In 1998 scientists started to systematically analyze the likelihood of Lithopanspermia by performing suitable experiments. The Mars-Earth System served as a model system in these studies. Because ► [Mars](#) is similar to Earth in many aspects and may have had a similar early evolution and because of its proximity to Earth, it is conceivable that life may have originated on Mars and spread to Earth. The discussion was furthered by the albeit controversial discovery of fossil nanostructures in the Martian meteorite ► [ALH 84001](#) in 1996. In general, Panspermia could occur if: (1) rock hosting microorganisms from an inhabited “home” or “donor” planet was ejected into space; (2) the ejected material traveled a potentially long time (about thousands to millions of years) through space without disintegration of the life forms; and (3) the host rock entered into the atmosphere of a habitable “acceptor” planet where the ► [microorganisms](#) would come back to life and replicate. All three elements of the scenario have been thoroughly tested and additional tests are still in progress. Crater impact researchers have provided data on shockwave pressures that will be reached in the spallation zone during an impact

event. Studies of craters on Mars are the basis of this data and have helped to get the most realistic conditions for impact simulation experiments. The shockwave experiments were run by shooting into (Mastrapa et al. 2001), or by the use of explosive devices on rocky material hosting microorganisms, creating realistic simulation of asteroid impacts, which are reaching according to calculations of shockwave pressures up to 50 GPa (Stöffler et al. 2007; Horneck et al. 2008). The results of these experiments showed that the tested microorganisms such as ► [bacteria](#) and ► [lichen](#) spores survived. The second step of the Panspermia scenario was tested by ground-based space simulations and by space exposure experiments on ESA or NASA space hardware devices like ► [BIOPAN](#) mounted on the satellite FOTON and launched by Soyuz rockets (de la Torre et al. 2010), or by the exposure platforms ► [EXPOSE-E](#) and [EXPOSE-R / -R2](#) on the ► [International Space Station](#) launched by Space Shuttles or Soyuz rockets (Cottin et al. 2015, 2017; de Vera et al. 2019). The results of these experiments support the Lithopanspermia hypothesis. But tests of the entry part of the hypothesis in an experiment named ► [STONE](#) using the reentry devices of the FOTON satellite were negative because the tested organisms failed to survive. New tests using satellite reentry devices are planned for the near future. To better design realistic experiments, it is important to consider that various models of Panspermia exist.

Basic Methodology

The three elements of (Litho-)Panspermia can be studied by using ► [asteroid](#) impact simulation devices and space exposure platforms. Asteroid impact events producing shockwaves are achieved by experiments using explosive devices or projectile experiments. Further steps of Panspermia are checked by space exposure tests on space exposure platforms like ISS or FOTON and by reentry experiments that are performed on reentry devices of satellites like the FOTON capsule.

Key Research Findings

The performed Panspermia experiments have shown that besides very resistant prokaryotic microorganisms (bacteria and archaea), even eukaryotic microorganisms (lichens and spores of fungi) are able to survive asteroid impact events and space travel, whereas the reentry process seems to be the most harmful for both of these groups of microorganisms.

Future Directions

Experiments on verification or falsification of the Panspermia hypothesis are ongoing using various organisms and species. Especially the reentry experiments are not completed, and new sets of tests are still in progress.

Parallax

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

In astronomy, parallax is the apparent difference in angular position of a celestial object with respect to background stars, as seen from different positions as the Earth travels along its orbit around the Sun (and in recent times, as the Sun moves in its orbit around the center of our Galaxy). As a tabulated quantity for stars (the annual parallax), it is equal to the angle subtended from a star by the mean radius of the Earth's orbit. The farther the star, the smaller the parallax. The inverse of the parallax is thus a direct measurement of the

distance of a star, which is usually expressed in ► [parsecs](#). A parsec is the distance for which the annual parallax is 1 arc sec. Historically, parallax was the first reliable way to determine distances to nearby stars, and it remains a key technique today, with the use of spacecraft such as ► [Hipparcos](#). Radio astronomers have used VLBI techniques to accurately measure parallax and hence distances, for example, to the center of the Milky Way. Units: arc second.

Paralogous Gene

David Moreira and Purificación López-García
Unité d'Ecologie, Systématique et Evolution
CNRS UMR8079, Université Paris-Sud 11, Paris,
France

Synonyms

[Paralog](#)

Definition

Paralogous genes (or paralogs) are a particular class of homologous genes. They are the result of gene duplication and the gene copies resulting from the duplication are called paralogous of each other. After duplication, the paralogous genes can keep the same function (for example, the multiple

copies of ribosomal RNA genes found in many genomes), but they often diverge and develop different functions (for example, the translation elongation factors Tu and G). Paralogous genes can be retained in the genome after their duplication, but some copies can also be lost. This can generate complex patterns of presence/absence of the different paralogues that may render very difficult the interpretation of ► [phylogenetic trees](#), leading sometimes to erroneous inferences about the relationships between species. This is usually called the “hidden paralogy” problem.

Parametric Release

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

Parametric release is an alternative to end-product sterility testing of articles that have undergone sterilization processing. In general, to authorize the release of a product, a manufacturer performs tests and analysis on the final product. For parametric release, instead of testing each end product (which is difficult for high-volume items, and risks contaminating a now-sterile article), checking the parameters of the various

sterilization processes used during the production is deemed sufficient, if those processes have been certified. For example, parametric release is accepted by the US Food and Drug Administration for certification of many pharmaceutical products for injection. Parametric release is permitted based on objective evidence that the processes have been performed successfully; this includes monitoring of the process, documentation, and verifying that in-process data matches the predefined specifications. A similar approach is adopted for the planetary protection discipline, where sterilization/bioburden reduction credit is given based on verifying in-process data.

Parent Body

Jacques Crovisier
LESIA, Observatoire de Paris, Meudon, France

Keywords

Asteroid · Comet · Meteor · Meteorite · Meteoroid · Planet

Definition

A parent body is the object from which a given ► [meteorite](#) or meteoroid was ejected. Most meteorites come from the fragmentation of asteroids following collisions. Meteor showers are due to sizable dust particles shed by ► [comets](#).

Overview

With the exception of lunar and Martian meteorites, it is believed that most meteorites are derived from parent bodies in the ► [asteroid](#) belt. This

idea progressively emerged in the mid-nineteenth century from the works of Robert P. Greg (1826–1906), Auguste Daubrée (1814–1896), and Adolphe Boisse (1810–1896) (see Marvin [2006](#)).

There is a large diversity among both meteorites and asteroids. However, few specific asteroids are firmly identified as parent bodies. The comparison of spectral and mineralogical characteristics is basically hampered by the alteration of the asteroid surfaces by space weathering. The problem is further complicated because present asteroids may not be primordial, but the product of collisions themselves.

Could some meteorites, such as carbonaceous chondrites, be coming from comet nuclei? As was discussed by Campins and Swindle ([1998](#)) the question is still open. The specific case for the Orgueil meteorite, which could have come on a comet-like orbit, was studied by Gounelle et al. ([2006](#)).

The connections between comets and meteor showers, based upon orbital considerations, are easier to establish. The first link was obtained by Giovanni Schiaparelli (1835–1910) who related 109P/Swift-Tuttle and the Perseid meteors. This is now well-documented for most meteor showers (Jenniskens [2006](#)), which are related to present or extinct comets, or near-Earth asteroids.

A cheap way to study extraterrestrial matter, in contrast to costly sample return space missions, is to analyze this matter provided in the form of meteorites on the Earth's surface or of meteoroids or stratospheric dust particles in the Earth's atmosphere. It is therefore of paramount importance to relate this material to its parent bodies.

WISPR	Wide-field Imager for Solar Probe
SWEAP	Solar Wind Electrons Alphas and Protons
ISIS	Integrated Science Investigation of the Sun energetic particle
SPC	Solar Probe Cup
SPAN	Solar Probe ANalyzers

Definition

Parker Solar Probe is a NASA mission designed to investigate the fundamental plasma physics of the near-Sun plasma environment by flying into its outermost atmosphere known as the corona, a region which has never been explored before. It will perform the closest-ever in situ and remote sensing observations of the coronal and solar wind plasma as close as 9.8 solar radii (Rs) from the center of the Sun (0.045 A.U.).

History

The idea of the Parker Solar Probe mission dates back to the 1958 Simpson Committee Report which proposed several space missions including “a solar probe to pass inside the orbit of Mercury to study the particles and fields in the vicinity of Mercury.” The concept of this mission, originally called “Solar Probe” has been revised many times over more than five decades, nevertheless its main objective has always been a close encounter with the Sun.

It is only until 2014 that “Solar Probe” mission was confirmed and started to be developed as part of NASA’s Living with a Star (LWS) Program. In 2017, the spacecraft was renamed “Parker Solar Probe” in honor of the solar astrophysicist Eugene Newman Parker who developed the theory of the supersonic solar wind and predicted the “Parker spiral” shape of the solar magnetic field.

Overview

Parker Solar Probe (PSP) is a NASA mission that was launched on August 12, 2018, from Cape Canaveral, Florida, in the USA, to explore for the first time the Sun’s outermost atmosphere, known as the corona. PSP will fly through the expanding solar corona to understand the underlying fundamental processes as close as 9.8 solar radii (Rs) from the center of the Sun (0.045 A.U.).

The primary science objectives of PSP are to: (1) trace the flow of energy that heats the corona and accelerates the solar wind; (2) determine the structure and dynamics of the magnetic fields at the sources of the fast and slow solar wind; and (3) determine what mechanisms accelerate and transport energetic particles.

It is important to study the Sun in order to understand how life on Earth developed. In addition, the knowledge of the space environment is a necessity to protect spacecraft and astronauts.

In order to unlock the mysteries of the solar corona and so to complete the mission science objectives, PSP performs 24 elliptical orbits around the Sun over a 7-year nominal mission duration. Moreover, it uses seven Venus gravity assists to gradually reduce its perihelion from about 35 Rs (0.16 AU) for the first orbit to 9.86 Rs (0.0459 AU) in the final three orbits.

The PSP payload includes a combination of four in situ and remote sensing instruments to observe the magnetic and electric fields, the plasma, and the energetic particles. These observations will expand our knowledge of the origin and evolution of the solar wind and revolutionize our understanding of the solar corona. The four suites of instruments are FIELDs, WISPR, SWEAP, and ISIS investigations.

1. FIELDs consortium (Bale et al. 2016): It consists of two fluxgate magnetometers (MAG), a search coil magnetometer (SCM), and five electric antennas. This experiment aims to measure the magnetic and electric fields, and indirectly infers the electron density using the plasma quasi-thermal noise spectroscopy.
2. WISPR (Wide-Field Imager for Solar Probe, Vourlidas et al. [2016]): This experiment is the

only imaging instrument aboard the spacecraft. It is a white-light telescope that capture images of the solar corona and inner heliosphere, including images of the solar wind, shocks, and transient structures as they approach and pass by the spacecraft.

3. SWEAP (Solar Wind Electrons Alphas and Protons, Kasper et al. [2016]): This experiment comprises two electrostatic analyzers (Solar Probe Analyzers, SPAN-A and SPAN-B) and a Faraday cup (Solar Probe Cup, SPC) to measure the electrons, protons, and helium ions in the solar wind and coronal plasma. Moreover, it can determine their bulk properties such as velocity, density, and temperature as well as full 3D distribution functions.
4. ISIS (Integrated Science Investigation of the Sun Energetic Particle, McComas et al. [2016]). This instrument suite comprises two independent energetic particle instruments (EPI-Hi and EPI-Lo, where EPI stands for energetic particle instrument) covering different and overlapping energy ranges to measure the flux of energetic protons, electrons, heavy ions, and their distribution functions (10 keV to 100 MeV).

Pasteurization

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

[Pasteurization is the name given to a particular heat-treatment process that reduces the number of viable microorganisms (typically by a factor of 10^5) but does not necessarily bring the number of remaining organisms to zero. This process is applied mainly to food products of known microbial cleanliness level, using moderate temperatures (under 100 °C). It is not approved as a standard process for planetary protection to reduce the bioburden on thermosensitive components but could be proposed for use for specific mission applications.

Peptidoglycan

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Definition

Peptidoglycan is a polymer with a structural role in the bacterial ► [cell wall](#). It is a barrier that provides structural strength to the ► [bacteria](#). It is made of polysaccharides attached to oligopeptides in linear chains (*N*-acetylglucosamine and *N*-acetylmuramic acid alternating with cross-linked oligopeptides (no more than five amino acids)). The oligopeptides are attached to *N*-acetylmuramic acid. Due to the cross-linked oligopeptide, it constitutes a 3D structural layer, which is thicker in the case of ► [Gram-positive bacteria](#) (Fig. 1).

Peptidoglycan, Fig. 1 Peptidoglycan basic monomer with two elements (*N*-acetylglucosamine and *N*-acetylmuramic acid). Cross-linked oligopeptide constitutes a 3D network with structural role in the bacterial cell wall

Perchlorates on Mars

Daniela Tirsch¹ and Alessandro Airo²

¹German Aerospace Center DLR, Institute of Planetary Research, Berlin, Germany

²Institut für Geologische Wissenschaften Tektonik und Sedimentäre Geologie, Freie Universität Berlin, Fachbereich Geowissenschaften, Berlin, Germany

Definition

Perchlorates are salts derived from the perchlorate acid (HClO₄). They form through oxidative processes in the atmosphere and accumulate with the dust (Smith et al. 2014). In 2008 perchlorates were detected by the Phoenix lander in the Martian soil. Sample analysis by the NASA rover “Curiosity” at Gale crater suggest the presence of perchlorates in an aeolian dune at the location called “Rocknest”. Perchlorates are of particular relevance in terms of ► [Habitability on Mars](#) because they could oxidize and therefore decompose possible organic compounds. Furthermore, on Earth perchlorates found in the Atacama Desert have been shown to serve as Nutrients for microbes.

Permafrost

Daniele L. Pinti
Geotop, Research Centre for the Dynamics of the
Earth System, Université du Québec à Montréal,
Montréal, QC, Canada

Synonyms

[Perennially frozen ground](#)

Definition

Permafrost is soil that remains below the freezing point of water (0 °C) for more than two consecutive years. It is mainly located at high latitudes (24% of the exposed land in the Earth's northern hemisphere) and high altitude (alpine permafrost). Permafrost exists at all latitudes on Mars and subsurface ice probably is abundant. Asteroid 25143-Itokawa and Eros show surface morphologies that suggest the occurrence of a permafrost and occasionally meltwater. Earth's permafrost is a site of microbial activity within thin films of liquid water between ice and soil particles. The occurrence and distribution of these microbial communities are studied as possible analogues of life forms on icy planets and satellites of the Solar system.

Permeability

David Deamer
Department of Chemistry, University of
California, Santa Cruz, Santa Cruz, CA, USA

Keywords

Bilayer · Concentration gradient

Definition

Permeability is a measure of the ability of a fluid or gas to pass through porous solids or aggregates. In the biological sense, it also refers to the relative ability of solutes to diffuse through the ► [lipid bilayer](#) barrier of ► [membranes](#). Biological membranes and lipid vesicles are relatively permeable to small, uncharged molecules such as water,

carbon dioxide, and oxygen, and relatively impermeable to ionized solutes like sodium, potassium, chloride, and ► [amino acids](#).

Overview

All cellular life is defined by boundary membranes that provide a selective barrier to the free diffusion of solutes such as ions (sodium, potassium, chloride, phosphate, protons) and nutrients (glucose, amino acids). The permeability barrier is the lipid bilayer, and cells have evolved a variety of ► [proteins](#) that act as channels and transporters to select which solutes can enter or leave a cell. The rate at which a given solute crosses the bilayer barrier is usually expressed in terms of a permeability coefficient (P), which by convention is defined as the amount of solute crossing a square centimeter of membrane in 1 s down a unit concentration gradient. A simplified equation for the permeability coefficient is $P = J/\Delta C$, where J is the flux in $\text{mol cm}^{-2} \text{s}^{-1}$, and ΔC is the difference in concentration driving the flux in mol cm^{-3} . The units are then cm s^{-1} . A typical measurement of the permeability coefficient of water is 10^{-3}s^{-1} , whereas the permeability of an ion such as potassium is $10^{-11} \text{cm s}^{-1}$, which is eight orders of magnitude lower. A more intuitive way to think about permeability is in terms of the half-time of decay of a gradient. For instance, water permeation across liposome membranes has a half-time measured in milliseconds, while the decay of a potassium gradient in the same system is measured in hours.

Solute have two mechanisms for crossing a lipid bilayer barrier. The simplest mechanism is referred to as solubility-diffusion, in which the solute dissolves in the hydrocarbon phase and diffuses to the other side where it dissolves in the opposite bulk phase. Small neutral molecules, like water and gas molecules, pass through the membrane barrier by this process. The other mechanism involves transient or permanent transmembrane defects. For instance, membranes would be virtually impermeable to ionized solutes such as potassium ions due to the Born energy required for an ion to move from a high dielectric polar solvent like water to a low dielectric phase such as the nonpolar

interior of a lipid bilayer, which is composed of hydrocarbon chains. However, ions can penetrate the lipid bilayer by passing through transient defects that constantly appear and disappear in the bilayer. The protein channels in biological membranes overcome the Born energy barrier by providing a permanent high dielectric pathway through the hydrocarbon chains.

Selective permeability to solutes is an essential property of cell membranes today, and must also have been important to the first forms of cellular life. It is likely that primitive cell membranes were composed of short chain amphiphilic molecules available in the prebiotic environment, which would be much more permeable than the evolved membranes of cells today. Therefore, the function of membranes in the first forms of life would be to maintain large polymers within a compartment so that they could interact, while allowing access to nutrient solute molecules such as amino acids.

Peroxisome

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

A peroxisome is a membrane-enclosed ► [organelle](#) present in almost all eukaryotic cells, whose

function is to produce hydrogen peroxide (H_2O_2) from the reduction of O_2 by various hydrogen donors. They participate in the metabolism of fatty acids and many other metabolites. The hydrogen peroxide produced in the peroxisome is degraded to H_2O and O_2 by the enzyme catalase. Peroxisomes are bound by a single membrane that separates their contents from the cytosol and contains membrane proteins involved in different functions (transport, proliferation). Peroxisomes originate in the cell by incorporating their proteins and lipids from the cytoplasm, eventually becoming a membrane-enclosed entity that can enlarge and divide in synchrony with the cell. Peroxisomes are absent in prokaryotic organisms.

Mars · Rover · Mars sample return ·
Exploration Astrobiology

Definition

Perseverance is the name of the rover of the → NASA mission to → Mars named → MARS 2020. The mission has been launched on July 28, 2020, by an Atlas V rocket. The rover landed safely, at the surface of Mars in Jezero Crater, February 18, 2021. The rover is designed to perform scientific research and to collect Martian samples to be sent to Earth in the next decade. It is equipped with seven science instruments, one demonstrator to produce locally molecular

oxygen (O_2), and a system to collect, seal, and store sample tubes. Additionally, → Ingenuity, a small helicopter was released from the body then tested to demonstrate the feasibility of flying within the Martian rarefied atmosphere.

History

In July 2013, a science definition team for the next mission to Mars, set up by NASA, issued the science objectives and exploration priorities for the next NASA robotic mission to Mars (Mustard et al. 2013). The launch date target was set for 2020.

September 24, 2013, NASA issued an Announcement of Opportunity (AO) for the instruments of the science payload of the new Martian rover which will be similar to →

Curiosity. The AO was open as usual to foreign contributors as long as they are sponsored by their national institutions.

NASA received 58 proposals and announced by July 31, 2014, the seven selected instruments. The development of the composite spacecraft including the sky crane and the rover is based on the heritage of Curiosity, while the instrumentation is essentially new.

Overview

Perseverance is a six wheel vehicle weighting 1025 kilograms on Earth (Fig. 1). The vehicle is roughly 3 m long and 2.7 m wide. It is equipped with a 2.1 m long robotic arm holding a 45-kilogram turret at the end. It has also a mast carrying several instruments and cameras, topping

Perseverance, Fig. 1 NASA's Perseverance Mars rover selfie with the Ingenuity helicopter, seen here about 3.9 m from the rover in this image taken April 6, 2021, by WATSON the camera of SHERLOC. Credit NASA/JPL-Caltech/MSSS

at 2.2 m. The energy, about a continuous 110 W flow, is provided by a Multi-Mission Radioisotopic Thermo-electric Generator (MMRTG) based on Plutonium 138 decay.

The science goals of Mars 2020 as described in the MEPAG report (Mustard et al. 2013) are split in four high level objectives: (i) to explore ancient environments of Mars to decipher the geological history of the planet; (ii) to evaluate the potential for eventual biosignatures in selected geological context; (iii) to collect relevant samples of Martian soil and atmosphere to be sent to Earth by future missions; and (iv) to prepare for future human exploration of the planet.

To fulfill these goals, the 59 kg scientific payload comprises seven instruments.

Mastcam Z (Bell et al. 2021) is a set of two cameras, focusable and zoomable to provide multispectral, stereo, and panoramic images of the environment. They are mounted on the remote sensing mast, at around 2 m above the Martian surface. Through a set of filters on wheels it produces broad band red/green/blue and narrowband 400–1000 nm images. The instrument lead is from the Arizona State University.

SuperCam (Maurice et al. 2021) based on the heritage of the ChemCam instrument is a suite of five techniques to analyze rocks and soil. The observation are performed through Laser-Induced Breakdown Spectroscopy (LIBS), Time-Resolved Raman and Luminescence (TRR/L), both sharing the same laser lamp, visible, and near-infrared spectroscopy (VISIR), high-resolution color imaging (RMI), and acoustic recording (MIC). The instruments operate at remote distances, primarily 2–7 m for LIBS, TRR/L, and up to the infinite for VISIR and RMI, while providing data and images at sub-mm to mm scales. SuperCam is mounted on the top of the remote sensing mast. This instrument is provided by a consortium led by Los Alamos National Laboratory (USA) with “Institut de Recherche en Astronomie et Planétologie” (France) and University of Valladolid (Spain).

Radar Imager for Mars Subsurface Exploration (RIMFAX), (Hamran et al. 2020) is a Ground Penetrating Radar to image subsurface structure, and to provide information regarding subsurface composition. The instrument is a Frequency Modulated Continuous Wave (FMCW) radar, which transmits a signal swept through a range of frequencies between 150 and 1200 MHz. The full bandwidth (effective center frequency 675 MHz) is used for shallow imaging down to several meters. Imaging deeper structures uses a reduced bandwidth of the lower frequencies, centered on the frequency 375 MHz. The instrument is built under the direction of the University of Oslo (Norway).

Scanning Habitable Environments with Raman and Luminescence for Organics and Chemicals (SHERLOC), (Barthia et al. 2021) is a Raman spectrometer and a camera mounted on the robotic arm. The Spectrometer produces spatially resolved chemical maps using fluorescence and Raman spectroscopy coupled to microscopic images (10.1 $\mu\text{m}/\text{pixel}$). The camera (WATSON) obtains color images from microscopic scales (13 $\mu\text{m}/\text{pixel}$) to infinity. SHERLOC Spectroscopy is based on a pulsed deep UV neon-copper laser (248.6 nm), giving a 100 μm spot on a target at a working distance of 48 mm. Fluorescence emissions from organics, and Raman scattered photons from organics and minerals, are analyzed with a single diffractive grating spectrograph with a spectral range of 250 to 370 nm. Because the fluorescence and Raman regions are naturally separated the Raman region 250 to 273 nm and the fluorescence region 274 to 370 nm are acquired simultaneously. The instrument is provided by the Jet Propulsion Laboratory (USA).

Planetary Instrument for X-Ray Lithochemistry (PIXL) (Allwood et al. 2020) is a microfocus X-ray spectrometer placed on the robotic arm. It provides within seconds the composition in major and minor rock-forming elements as well as some trace elements. The diameter of the X-ray beam is 120 μm . On several hours, the instrument can collect several thousand points of measurement, providing an elemental

map of a rock surface, correlated to the image acquired by the PIXL camera. The instrument is provided by the Jet Propulsion Laboratory.

Mars Environmental Dynamics Analyzer (MEDA) (Rodriguez-Manfredi 2021) is a set of meteorological sensors. Placed on the mast of the rover, it comprises a wind sensor, a barometer, a relative humidity sensor, and a set of five thermocouples to measure atmospheric temperature at about 1.5 m and 0.5 m above the surface. Some thermopiles characterize the thermal IR brightness temperatures of the surface and of the lower atmosphere. MEDA monitors also the optical atmospheric properties to determine bulk aerosol physical parameters. The instrument is provided by Centro de Astrobiologia, (Spain).

Mars Oxygen ISRU Experiment (MOXIE) (Hecht et al. 2021) verifies that it is possible to produce molecular oxygen dissociating atmospheric carbon dioxide. This technological demonstrator is based on solid oxide electrolysis of heated CO₂. The anode is producing almost pure oxygen while the cathode is concentrating the carbon monoxide (by-product of the method) and other atmospheric gases. The production could deliver up to 6 g/h of 98% pure molecular oxygen. The instrument is provided by the Massachusetts Institute of Technology (USA).

Finally the rover is equipped with a complex and sophisticated sampling and caching system (Moeller et al. 2021) to take samples, to preserve, and to store them in dedicated sample tubes and finally deliver them on the ground, at the appropriate time and location, to be retrieved by a future European Fetch Rover. Perseverance is the actual first leg of the International → Mars sample return program.

Because it is landing on Mars, searching for biosignatures and preparing a restricted sample Earth return, the rover and its payload have to follow stringent rules to be in agreement with the → Planetary Protection Policy addicted by COSPAR and adopted by the USA.

In addition, perseverance is carrying a small helicopter, →Ingenuity to demonstrate the possibility to fly in the tenuous atmosphere of Mars and explore how this kind of device can help either for the robotic or future manned exploration of the red planet.

pH

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Synonyms

[Hydrogen ion concentration index](#)

Definition

pH describes the activity of hydronium ions (H_3O^+ , or more precisely the hydrated form of the proton H^+ in solution) in aqueous solution. pH characterizes the acidity or basicity of aqueous solutions. It is formally defined by the relation:

$$\text{pH} = -\log_{10} a_{\text{H}}$$

in which a_{H} is the activity of the solvated hydronium ion. The pH of an acidic solution is less than 7, and the pH of basic solution is greater than 7 at 25 °C, but pH values change as a function of temperature.

Phase Transition

Henderson James Cleaves
Earth-Life Science Institute (ELSI), Tokyo
Institute of Technology, Meguro-ku, Tokyo,
Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

Matter in the universe generally exists in one of four phases (states in which matter has essentially uniform physical properties): plasma, gas, liquid, and solid. The transition between each phase has an associated name (Fig. 1). Transitions can also occur within the solid phase.

The transition of matter between phases may be exergonic or endergonic. The change in energy is due to the change in interactions and ordering of the atoms or molecules and the associated changes of entropy and/or enthalpy (e.g., upon the freezing

Phase Transition, Fig. 1 The four phases of matter and the transitions between them

of a liquid phase, in which the components are highly mobile (with higher entropy), to a solid phase in which the components are in relatively fixed positions (with lower entropy)).

When a phase change occurs at a constant temperature, the energy required to cause the phase change (in the case where such a change is not spontaneous or energetically favorable), or the energy liberated (in the case where a phase change is spontaneous) is referred to as the latent heat. The value of this quantity is specific to the type of material in question (i.e., the latent heat of water is different than the latent heat of lead).

Phase, Orbital

David W. Latham
Harvard-Smithsonian Center for Astrophysics,
Cambridge, MA, USA

Definition

For an object in a periodic orbit, the phase is the fraction of period that has passed since the time

$t = 0$. Mathematically, the location of $t = 0$ can be any arbitrary point on an orbit; however, in Keplerian orbits, the point of ► [periastron](#) is considered as the location of $t = 0$. Usually, the phase is measured from the most recent periastron passage, but sometimes the phase will include an integer count for the number of orbital cycles since a fiducial periastron passage. For a circular orbit, the usual convention is to define phase zero as the time of maximum radial velocity of recession for the more massive component.

Cross-References

- [Periastron](#)

Phenetics

Carlos Briones
Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Synonyms

[Numerical taxonomy](#)

Definition

Taxonomical analysis aimed at classifying organisms with respect to their ► [phenotype](#). It considers the overall similarities in observable/measurable characters – such as morphology or metabolic traits – among organisms or biological taxa regardless of their phylogenetic or evolutionary relationships. Phenetic techniques include various forms of clustering. They measure a – usually large – number of variables, analyze them by mathematical and statistical means to reduce them to a manageable level, and generally produce two- or three-dimensional graphs where different clusters of phenotypes are located.

Phenotype

Susanna Manrubia

Systems Biology Program, Centro Nacional de Biotecnología (CSIC), Madrid, Spain

Keywords

Adaptation · Environment · Genotype · Morphology · Natural selection · Survival

Definition

The phenotype of an organism is the collection of all its observable characteristics, such as morphological traits, physiology, or behavioral properties. The phenotype arises from the interaction of the total genetic inheritance of each organism with the ► [environment](#) where it develops and grows, and might change during its life due to aging processes or environmental changes. In its turn, the phenotype determines how suited an organism is to survive and reproduce in a given environment. In the case of a virus, the phenotype refers mainly to the effects it causes in the infected host. The phenotype of a molecule consists of its structure and chemical function.

Overview

The relationship between ► [genotype](#) and phenotype is essential to understand how biological evolution proceeds. The distinction between the hereditary and developmental pathways as causally separated processes dates back to 1911 (Johannsen 1911): the genome is inherited,

while the phenotype is its final expression under the environmental conditions specific to an organism. While innovations in biological evolution result from unintentional changes (► [mutations](#)) at the genomic level, ► [natural selection](#) can only act on the phenotype. Therefore, phenotypic variation is a prerequisite for evolution by natural selection.

The genotype-phenotype map is a many-to-many relationship, and as such it is only partly deterministic. One genotype might produce different phenotypes, since not all inherited possibilities are expressed. Plants growing in different watering conditions, for instance, are able to adjust their size and the shape of their leaves. Another example is that of certain proteins – fully functional in their native folded state – that become infectious agents (► [prions](#)) when mis-folded. Even identical human twins differ in their fingerprints, and behave distinctly as a result of nurture. The environment-dependent expression of genotype (a one-to-many relationship) is called phenotypic plasticity (De Witt and Scheiner 2004). On the other hand, the construction of an organism from genotype to phenotype displays a great amount of redundancy (a many-to-one relationship). Redundancy is an essential property conferring robustness when organisms face endogenous or exogenous change, fluctuations, or randomness. The neutral theory of molecular evolution (Kimura 1983) analyzes the important role of a huge number of mutations present in the genotype that do not have an effect on phenotype (beyond changing the genomic sequence) but strongly affect the population structure and its intrinsic diversity, and thus its ability to adapt to new environments. The extent to which changes in genotype do not affect phenotype is called genetic canalization (Rendel 1967; Jen 2005).

The concept of extended phenotype (Dawkins 1982) refers to all the effects a gene can have upon the world which influence its chances of ► [survival](#), thus extending beyond the genome-carrying individual organism. Examples are dams constructed by beavers, the elaborately woven nests of weaver birds, or the behavior a parasite can induce upon an infected host.

Phenylalanine

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Definition

Phenylalanine is one of the 20 protein ► [amino acids](#) whose chemical structure is NH₂—CH

(CH₂C₆H₅)—COOH. Its three-letter symbol is Phe, and one-letter symbol is F. Its molecular weight of 165.19, and its isoelectric point (pI) is 5.48. It shows poorer water solubility than most of the other amino acids. Since its side chain is a benzyl group (—CH₂C₆H₅), it is grouped as an aromatic amino acid together with tyrosine and tryptophan. ► [Proteins](#) present a UV absorbance at 280 nm because of the UV-absorbing aromatic rings present in these amino acids. Phenylalanine has recently been detected in extracts from Antarctic carbonaceous chondrites.

Philae Lander

Hervé Cottin
Univ Paris Est Creteil and Université de Paris, CNRS, LISA, Créteil, France

Keywords

Lander · Rosetta · Comet · 67P/Churyumov-Gerasimenko

Definition

Philae is the lander of the ESA Rosetta mission, which landed and bounced on the nucleus of comet 67P/Churyumov-Gerasimenko on November 12, 2014.

Overview

Philae is the first automated vehicle that landed on the nucleus of a comet. It is part of the European mission ROSETTA. Its overall mass is 98 kg including a scientific payload of 27 kg.

The name of the lander follows the name of a Nile island where an obelisk was found, whose association with the Rosetta stone helped Champollion to understand the meaning of hieroglyphs.

On November 12, 2014, the Philae lander was released from its mother spacecraft at a distance of about 3 AU from the Sun and 20 km from the surface of comet 67P/Churyumov-Gerasimenko to land after 7 h of free fall. The landing site (called Agilkia) was a relatively smooth terrain on the smaller lobe of comet 67P. Contact with the nucleus was reported at 15:34 UTC. However, it turned out that the lander did not anchor at the surface and bounced twice on the comet before making it to its final landing site after 2 h hovering above the nucleus in its low gravity environment. There, not sufficiently illuminated by the Sun, it could rely only on its primary battery to achieve its first science measurements sequence. After 64 h of operations at the comet's surface, Philae went into safe mode due to lack of power. For a while, hopes remained that it could wake up again and proceed to new measurements when the comet is closer to the Sun, with a better orientation to provide sufficient energy to the solar panels of Philae. Some very limited communication could indeed be established from June 13 to July 9, 2015, showing that the lander had sufficient illumination to reboot out of the safe mode. However, the communication was too sporadic to allow any operation of the lander for science. Later, no communication could be established, and the reason for the poor transmission quality between the spacecraft and the lander is still unclear. Finally, close to the end of the Rosetta mission, a picture of Philae was taken from the Rosetta spacecraft on September 2, 2016. It showed Philae on its side, underneath a cliff. Its final site has been called Abydos.

Phobos

Harald Hoffmann

DLR, Institute of Planetary Research, Berlin, Germany

Definition

Phobos is the inner of the two Martian satellites that were discovered by Asaph Hall in 1877. It is in nearly circular synchronous (Phobos's; length of day and orbital period are identical) orbit around ► [Mars](#) with an average distance of 9375 km to the center of the ► [planet](#) and an orbital period of 0.32 days (Jacobson 2010). Phobos measures $26.8 \times 22.4 \times 18.4$ km; it has a bulk density of about 1.9 g/cm^3 . The heavily cratered surface indicates an old formation age. Two hypotheses are actually discussed to explain the origin of Phobos: capture of a D-type ► [Asteroid](#) or reaccrction of Martian ejecta.

Phobos soil

Definition

Phobos-Grunt is a mission to ► [Phobos](#), one of the two small satellites of ► [Mars](#); it was developed by the Russian agency ► [Roskosmos](#), with the participation of other countries to the science payload. Launch occurred in Baikonur, on November 8, 2011, for an arrival end-2012, and a landing on Phobos mid-2013; the payload consisted in Phobos-Grunt and ► [YingHuo-1](#), a Chinese satellite, intended to study Mars and Phobos. One of the goals of Phobos-Grunt was to proceed to in situ soil analyses, to help understand the composition of Phobos (structure, mineralogy, organic matter), hence its origin. About 200 g of soil samples should have been sent from Phobos to Earth, for a landing in 2014. Unfortunately, due to some concerns in the cruise stage, the probe was unable to leave its elliptical orbit around the Earth, and to begin its cruise to Mars and Phobos. After orbiting for 2 months, it disintegrated while entering Earth dense layers of the atmosphere, and the debris fell in Pacific Ocean. The idea of a return to Phobos exists, this reflight should mainly utilize spare models of the experiments that were on the previous probe.

Overview

Due to its low ► [albedo](#) and spectral characteristics (Murchie and Erard 1996; Simonelli et al.

1997), Phobos could be identified as a captured ► [asteroid](#), with a composition close to the organic-bearing carbonaceous chondrites (Rivkin et al. 2002); nevertheless, its low apparent density (1.9 g/cm^3) (Avanesov et al. 1991) leads to think that it could contain water ice (Christensen et al. 1977) or have a “rubble pile” structure (Murchie and Erard 1996). This possible porosity (25–35%) could also be explained by an origin at the moment of Mars’ formation, or as the result of an asteroidal impact on Mars. Phobos’s surface is covered by impact craters: near the rim of the huge crater Stickney, for example, “blue” material indicates material that possibly originates at depth (Fig. 1).

Twenty years after the USSR’s Phobos 1 and 2 missions, Roskosmos developed Phobos-Grunt (P-G), to be launched in 2011 (Zelenyi et al. 2010). It will carry the Chinese satellite Yinghuo-1, devoted to Mars study, and it will land on Phobos in April 2013 (Figs. 2 and 3).

The in situ science payload of the P-G lander (Zelenyi et al. 2010) resembles those of MSL and ► [Exomars](#). Its 40 kg includes, among others, cameras, radar, and seismometer to understand Phobos structure, and classical in situ instruments searching for elementary and mineralogical composition (Mossbauer, APX, IR, γ and n spectrometers, laser ablation mass spectrometer). The Gas Analytical Package will proceed to analyze soil samples, delivered by the P-G manipulator arm, possibly using a drill. Heating and pyrolysis of these samples, followed by analysis of evolved gases (► [GC-MS](#) and IR laser spectroscopy), will detect the presence of any water ice (Christensen et al. 1977) and the structural gases of the minerals (H_2O , CO_2 , etc.). Using the same techniques, this instrument will be able to search for ► [noble gases](#), ► [organic molecules](#) (nature, ► [isotopic ratios](#)) present in the ground, to be compared to the ones present in ► [meteorites](#) (Rivkin et al. 2002), to give clues on the origin and history of Phobos. Once landed, P-G will also sample the ground and bring to Earth (arrival July 2014; Galimov 2010) about 200 g of material, in a devoted container (see Fig. 3: small brown sphere on top of P-G) for further analyses.

P

The experiment Living Interplanetary Flight Experiment (LIFE) proposed by a US nonprofit association (the Planetary Society) will sit in the Phobos sample return capsule. Two titanium containers specially designed by the Russian Institute for Medico-Biological Problems will house terrestrial organisms (like seeds) and microorganisms. Pure culture of known resistant microorganisms strains from the three

domains of life (Archaea, Bacteria, and Eukarya) will sit along a sample of a terrestrial natural soil. All this samples will be tested for survival upon their recovery with the Phobos samples and subsequently analyzed. The containers will mimic rock and this will be an attempt to evaluate the possibility of panspermia while those organisms will experience a 34-month round trip to Mars.

Phoebe

Therese Encrenaz

LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

Saturn's satellite Phoebe was discovered in 1899 by William Henry Pickering; it has been for a century the outermost known satellite of ► [Saturn](#). It orbits at about 13 million kilometers (or 215 Saturnian radii) from Saturn; its orbit is highly inclined and is retrograde, which suggests that Phoebe was captured, rather than having been formed together with Saturn. It may have

originated as a Kuiper Belt Object. Phoebe was first observed by Voyager 2 in 1981 and then extensively explored by the ► [Cassini](#) orbiter. Its diameter is 220 km and its density is 1.6 g/cm³. Phoebe might be the source of a tenuous external Saturnian ring, and might also be responsible for feeding the dark side of ► [Iapetus](#) with dark material.

Phoenix

Michel Viso
Innovaxiom, Paris, CX, France

Definition

Phoenix was launched for its cruise to Mars from Cape Canaveral by a Delta II rocket on August 4, 2007. The soft landing in the north polar region occurred on May 25, 2008. The five science instruments, provided by US institutions with contributions from the Max Plank Institute (Germany) and the Canadian Space Agency (Canada), examined water ice under the surface, checking if this place could support life. A meteorological station provided data on the atmosphere and the water cycle. After 5 months of operation, the power declined as the illumination by the sun decreased. The last brief signal was received on November 2, 2008. In early 2010, attempts to communicate with Phoenix failed. The hardware was not designed to survive the cold and ice-coating load of an arctic Martian winter. One of the main results is the hypothesis of the presence of carbonate and perchlorate as well as the evidence of subsurface ► [ice](#).

Phosphaethyne (HCP)

Didier Despois
Laboratoire d'Astrophysique de Bordeaux,
CNRS-Universite de Bordeaux, Bordeaux,
France

Synonyms

[HCP](#); [Methinophosphide](#)

Definition

Phosphaethyne is, with PN, PH₃, and the radical CP, one of the few molecules detected outside the Earth that contain phosphorus, an element that plays a crucial role in biochemistry (being part of the structural framework of DNA and RNA and being used to transport cellular energy). HCP is similar in many ways to hydrogen cyanide, HCN, as phosphorus is below nitrogen in the Periodic Table. In the laboratory, phosphaethyne is a reactive species that spontaneously and rapidly polymerizes.

History

Phosphaethyne has been detected by Agúndez et al. (2007) in the carbon-rich circumstellar envelope of the evolved star IRC +10216 (CW Leo).

Phosphates

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

Phosphates are minerals containing the tetrahedral PO_4^{3-} group, the most abundant of which is apatite $\text{Ca}_{10}(\text{PO}_4)_6(\text{X})_2$, where X is OH, F, Cl, or CO_3 . Apatite is the main repository of phosphate in the Earth's mantle and the crust, and is used by both vertebrates and invertebrates to build solid parts (skeletons). In natural waters, the phosphate anion is an essential nutrient entering nucleic acids, phospholipids, and the universal energy currency adenosine triphosphate (ATP). Surface waters are depleted in phosphate by organic productivity. At depth, phosphate strongly correlates with nitrate and the remarkably constant C:N:P proportions of phytoplankton (105:15:1) are known as the Redfield ratio. ► [Mid-ocean ridges](#) and sediments are net P sinks, whereas continents are the dominant source of oceanic phosphate.

Phosphine

Matthew A. Pasek

University of South Florida, Tampa, FL, USA

Synonyms

[Hydrogen phosphide](#); [Phosphorus hydride](#)

Definition

Phosphine, PH_3 , is a toxic, phosphorus gas at standard temperature and pressure, boiling at 185 K and freezing below 135 K. Relative to phosphate, the redox state of the phosphorus atom in phosphine is reduced to -3 . Phosphine is the most abundant, naturally occurring volatile phosphorus species, and has been detected in the atmospheres of the gas giants Jupiter and Saturn, in the atmospheric envelopes of giant stars, and as a trace constituent in the atmosphere of the Earth. Its terrestrial origin may be linked to microbial activity or to anthropogenic sources; hence, phosphine plays a small role in the phosphorus biogeochemical cycle. At low

temperatures (below 70–80 K), it can be trapped as a clathrate in water ice.

Phosphite

Matthew A. Pasek
University of South Florida, Tampa,
FL, USA

Synonyms

[H-phosphonate](#); [Phosphonate](#)

Definition

Phosphite (HPO_3^{2-}) is the anion of phosphorous acid (H_3PO_3), an oxide of phosphorus in which the phosphorus has a +3 valence state. In contrast to orthophosphate dissolved in solution, in phosphite one hydrogen atom is directly bound to the central P atom, instead of being bound through an O atom. Phosphite is more soluble in ocean water than phosphate. Oxidation of phosphite yields phosphate and, under certain conditions, also pyrophosphate and larger polyphosphates. Phosphite on the Earth may have originated from corrosion of iron-rich meteorites or from reduction of phosphate by lightning strikes or other high-energy events, and may have comprised some portion of the total phosphorus in the early Archean oceans.

Prebiotic chemistry

Definition

Phosphorus (P) is a key element for the development of life. However, its low cosmic abundance compared to the other biogenic elements (carbon,

oxygen, nitrogen, and sulfur) has significantly limited our knowledge about its chemistry in the interstellar medium. Thanks to recent advances in the instrumentation of ground-based radiotelescopes and spatial missions, we have attained a much better understanding about the formation of P-bearing molecules in star-forming regions and Solar System objects. The study the inheritance of the reservoir of P during the process of star and planet formation is essential to understand how P became prebiotically available at the dawn of our planet, allowing the origin of life.

Overview

Phosphorus (hereafter P) is a key biogenic element for the development of life. This is because compounds containing P, and in particular phosphates, are unique in forming large biomolecules, thanks to their extreme structural stability and functional reactivity. Phosphorus is one of the crucial components of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), phospholipids (the structural components of cellular membranes), and the adenosine triphosphate (ATP) molecule, which stores the chemical energy within cells. Moreover, P-compounds are also key catalysts and chemical buffers for the formation of nucleotides (Powner et al. 2009). However, while the P abundance in living organisms is relatively high, e.g., $P/H \sim 10^{-3}$ in bacteria, (Fagerbakke et al. 1996), the abundance of P in the Universe is several orders of magnitude lower: $P/H \sim 3 \times 10^{-7}$ (Asplund et al. 2009). This makes P one of the major limiting nutrients for the development of life, and raises the question of how the reservoir of P can become biologically available on planets, and in particular how became on the early Earth. To answer these questions, multiple efforts in the last years have tried to understand the chemistry of P in the molecular cradles of stars and planets, and also in comets, which are considered to be representative of the pristine Solar System material, and might have delivered key

prebiotic chemicals to the primitive Earth (Chyba and Sagan 1992).

P is generated in the interior of massive stars and it is injected into the interstellar medium (ISM) through supernova explosions (Koo et al. 2013). The low number of these stars helps to explain the relatively low cosmic abundance of P relative to other biogenic elements. Moreover, since P is a relatively heavy element (atomic mass of 31 Da), it is expected to be depleted on the surfaces of interstellar dust grains in the dense and cold ISM (Turner et al. 1990). Thus, the detection of P-bearing species in the gas phase of the ISM is challenging. Historically, this has limited the number of P-bearing molecules identified in space. However, in the recent years, thanks to the improvement of sensitivity of current ground-based telescopes and space spacecrafts, a plethora of new detections of P-bearing species has been possible, allowing us to significantly improve our understanding about the chemistry of interstellar and cometary P.

Basic Methodology

The search of P-bearing species in different astronomical sources of the ISM can be done using rotational spectroscopy, mainly at (sub)millimeter wavelengths, using single-dish radiotelescopes such as the IRAM 30 m telescope or the Atacama Pathfinder Experiment (APEX), and interferometric arrays such as the Atacama Large Millimeter/submillimeter Array (ALMA), and the Northern Extended Millimeter Array (NOEMA). The analysis of the observed spectra, which can be done assuming Local Thermodynamic Equilibrium (LTE) or non-LTE **conditions**, provides the molecular abundances of the P-bearing species, and also their excitation conditions.

In the case of comets, although molecular studies using rotational spectroscopy from ground-based radiotelescopes are also possible, the in-situ mass spectroscopy obtained by the European Space Agency (ESA) mission Rosetta have provided unprecedented details

about the molecular reservoir of the comet 67P/Churyumov-Gerasimenko.

The outcome of the observations (see details in the section below) has been compared with newly developed theoretical chemical models (e.g., Rivilla et al. 2016; Jiménez-Serra et al. 2018), with the goal of understanding how P-bearing molecules are formed in the natal environment of stars and planets, and how they might be transferred to planetary system objects like comets and our own Earth.

Key Research Findings

While the ion P^+ was early discovered in several diffuse clouds (Jura and York 1978), no P-bearing species have been detected so far towards these regions despite deep observational searches (Chantzios et al. 2020). In the circumstellar envelopes of evolved stars, several P-bearing species have been identified (PN, PO, CP, HCP, C_2P , and PH_3 ; e.g., Guelin et al. 1990; Agúndez et al. 2007; Tenenbaum et al. 2007; Halfen et al. 2008; Agúndez et al. 2014). However, detections in star-forming regions have been more elusive, with only two species detected so far. PN was identified towards a handful of sources in the late 1980s (Turner and Bally 1987), and more recently towards large samples of massive star-forming regions (Fontani et al. 2016; Fontani et al. 2019), and molecular clouds in the center of our Galaxy (Rivilla et al. 2018), and also towards the birth environment of Solar-like protostars (Lefloch et al. 2016; Bergner et al. 2019). After several unsuccessful efforts (e.g., Fontani et al. 2016), PO was detected towards both massive (Rivilla et al. 2016; Bernal et al. 2021) and low-mass star-forming regions (Lefloch et al. 2016; Bergner et al. 2019), and towards a molecular cloud in the Galactic Center (Rivilla et al. 2018). These detections, based on single-dish observations, showed that P is less depleted on the dust grains of star-forming regions than previously thought, with a depletion factor around 100. Both P-bearing species have very low excitation

temperatures ($T_{\text{ex}} < 20$ K; Rivilla et al. 2018; Fontani et al. 2019; Bergner et al. 2019), which indicates that they are sub-thermally excited. The non-LTE effects on the derived molecular column densities have been considered using available collisional coefficients, and no significant deviations with respect to the LTE analyses have been found (Bergner et al. 2019; Rivilla et al. 2020). Remarkably, PO is more abundant than PN in all the astronomical sources where both species have been detected so far, within a factor ~ 2 –8. Several works have found that the spectral profile of PN is similar to that of a typical shock-tracer such as SiO (Lefloch et al. 2016; Fontani et al. 2019), which suggests that shocks are an important agent on the interstellar chemistry of P, as suggested by Aota and Aikawa (2012). This idea was also supported by the results from a survey of molecular clouds in the center of the Galaxy, in which PN was only detected in those clouds whose chemistry is dominated by shocks (Rivilla et al. 2018). This work also found a clear correlation between the column density of PN and that of SiO, result that has been confirmed by additional observations towards a large sample of massive star-forming region in the galactic disk (Fontani et al. 2019). The first interferometric maps of the emission of P-bearing molecules in a star-forming region (Rivilla et al. 2020) have shown that PN and PO arises from several spots associated with post-shocked low-velocity gas in the cavity walls of a protostellar bipolar outflow, rather than from high-velocity and directly shocked gas in the outflow. As already indicated by previous single-dish observations, PO is more abundant than PN, with an increasing trend of the PO/PN ratio with the distance to the protostar. These observations favor a formation scenario in which the formation and PO/PN are governed not only by shocks, as previously proposed, but also by UV radiation from the protostar. While shocks are needed to sputter P from the surface of dust grains, photochemistry in the gas phase induced by UV photons efficiently forms PO and PN in the illuminated cavity walls, in agreement with the chemical models by Jiménez-Serra et al. (2018).

Regarding the detection of P-bearing molecules in our Solar System, phosphine (PH_3) has been observed in the atmospheres of Jupiter and Saturn (Bregman et al. 1975; Ridgway et al. 1976). P has been identified in meteoritic material in the form of the mineral schreibersite (Pasek and Lauretta 2005) and phosphoric acids (Schwartz 2006). More recently, the measurements of the ESA Rosetta mission claimed the presence of P in the comet 67P/Churyumov–Gerasimenko (Altwegg et al. 2016), which is predominantly in the form of PO (Rivilla et al. 2020). The P/O ratio derived in 67P is $(0.5\text{--}2.7) \times 10^{-4}$, close to the Solar value of 5.8×10^{-4} , which indicates that P is only slightly depleted in the cometary material. As found in star-forming regions, PO is more abundant than PN, by at least a factor of 10. Since it is thought that the chemical composition of the 67P comet is presolar, PO, among other volatiles, was already in the cometary ices prior to the birth of the Sun. Therefore, the cometary chemical budget was inherited from the natal environment of the Solar System, which is thought to be a clustered environment that likely also included massive stars (Adams et al. 2010). The predominance of PO as main carrier of P both in both star-forming regions and Solar-like objects such as the comet 67P, confirms this chemical thread during the whole process of star formation.

Since comets may have delivered a significant amount of prebiotic material to the early Earth (Chyba and Sagan 1992), the P reservoir measured in 67P (mainly in the form of PO), along with those in other comets, could have contributed to the prebiotically available P reservoir during the dawn of our planet. This can help to solve the known as the “phosphate problem” about the availability of inorganic phosphate on the early Earth. The most common form of P on our planet is mainly found in apatite minerals, which have high insolubility, and whose P was not available for prebiotic processes. To solve this scarcity of prebiotic P, alternative (extraterrestrial) sources of P have been proposed: cometary material (Rivilla et al. 2020), and also the water-soluble schreibersite, $(\text{Fe,Ni})_3\text{P}$, the major carrier of P in iron meteorites (Pasek 2008). Moreover, recent theoretical works have also explored the possible

injection of meteoritic P in rocky planets, including our Earth (Douglas et al. 2019).

Future Directions

The detection of new P-bearing species in the gas of star- and planet-forming regions (e.g., PH_3 , CP, PS) will significantly help us to constrain much better the chemistry of this key biogenic element in the ISM. Since P is cosmically low-abundant, these detections will surely require very deep observations of the current, and likely, the next generation of radiotelescopes. Moreover, more detections of PO towards a large sample of sources will help us to evaluate if the ratio $\text{PO/PN} > 1$ found in a handful of regions is ubiquitous in the Universe. As well, the study of the spatial distribution of the emission of P-bearing species with interferometers (e.g., ALMA) towards more sources will allow us to attain a much better knowledge about the possible physical mechanisms (e.g., shocks, photochemistry) that are responsible of the formation and destruction of P-bearing species in the ISM. In this regard, the further development of the few theoretical chemical models devoted to P will be absolutely needed. New plausible chemical routes should be explored, and their associated reaction rates should be derived theoretically and/or measured directly in the laboratory. Moreover, the study of spectroscopy of new P-bearing species might also allow its future detections in the ISM, completing our picture of the interstellar chemistry of P.

Phosphorus Hydride

- [Phosphine](#)

Phosphorus Monoxide (PO)

Didier Despois
Laboratoire d'Astrophysique de Bordeaux,
CNRS-Universite de Bordeaux, Bordeaux,
France

Synonyms

[PO](#)

Definition

Phosphorus monoxide is an unusual oxidized form of phosphorus, recently detected in the envelope expelled by an evolved star (the most common phosphorus oxides on Earth are P_4O_6 and P_4O_{10}). PO is, with HCP, PN, PH_3 , and CP, one of the few molecular species outside the Earth containing phosphorus, an element that plays a central role in biochemistry. The P—O bond is present in adenosine diphosphate (ADP) and adenosine triphosphate ([▶ ATP](#)).

History

Tenenbaum et al. (2007) detected phosphorus monoxide in the circumstellar shell of the oxygen-rich supergiant star VY Canis Majoris.

Definition

Photoautotrophs are organisms that obtain cellular [▶ energy](#) from radiation and assimilate CO_2 as a source of carbon. They differ from photoheterotrophs that produce ATP using solar energy but obtain carbon for biosynthesis from reduced organic compounds. The [▶ photosynthesis](#) reaction center of photoautotrophic organisms contains chlorophyll, a pigment responsible for the transduction of radiation into cellular energy. Photoautotrophs can be divided in two groups, anoxygenic and oxygenic, depending on the number of reaction centers in their photosynthetic apparatus and on their ability to use water as a source of reducing power and generating oxygen as a by-product. Anoxygenic photoautotrophs are dependent on environmental reducing power to assimilate CO_2 . From an ecological point of view, life on Earth has been considered to be dependent on photoautotrophy; however, the recent discovery of underground strict chemolithoautotrophs is challenging this concept.

Definition

Photobiology is the scientific discipline studying the effects of nonionizing radiation on biological systems – specifically ultraviolet, visible, and infrared radiation, either from the sun or from artificial sources.

Overview

Photobiological responses are the result of chemical and/or physical changes induced in biological systems by nonionizing radiation. The radiation spectrum covered by the discipline photobiology ranges from ultraviolet radiation with wavelengths from 10 to 400 nm to visible light from 400 to 750 nm to the infrared radiation from 750 nm to 300 mm.

The research topics in photobiology are very broad: Photobiology at the molecular and cellular level deals with photochemical reactions after the absorption of nonionizing radiation and the following biological responses in cells, e.g., enzymatic repair of UV radiation-induced DNA damage or the induction of the synthesis of photoprotecting compounds. Another research field is the investigation of bioluminescence, the production of light by biochemical cellular reactions in some bacteria, invertebrates, and vertebrates. Organisms had developed the ability to produce bioluminescence for signaling and communication purposes. In biotechnology, bioluminescence is used as a reporter signal for genetic engineering. Photosynthesis, the process of utilizing solar radiation and carbon dioxide for the synthesis of organic compounds in plants, algae, and some species of bacteria, is another important field of photobiological research. At the organism level, chronobiology examines periodic phenomena in living organisms and their adaptation to solar-related rhythms. Photocarcinogenesis research aims at the discovery of the complex simultaneous and sequential biochemical events in higher organisms that ultimately lead to the occurrence of skin cancer, in many cases several years after exposure. In photomedicine, the application of light with respect to health and disease is studied and used for therapy. Photomedical aspects can be found in various fields of medicine including dermatology, surgery, dentistry, optical diagnostics, cardiology, and oncology. Effects of solar radiation on ecosystem level are monitored and examined in environmental photobiology. In astrobiology, the early Earth's UV climate with wavelengths down to 200 nm penetrating the atmosphere to the Earth's surface was found to be a major driving force for biological evolution. Based on photobiological laboratory experiments in planetary and space simulation facilities and in space experiments in low Earth orbit like those performed in ESA's EXPOSE facilities on the International Space Station (ISS), the habitability of other planets, such as, Mars, with respect to a UV climate different from today's Earth is estimated.

Definition

Solid particles produced by photochemistry in planetary atmospheres.

Overview

Clouds and hazes are present in every atmosphere of the Solar System and they are expected to be common in exoplanetary atmospheres. For the planetary science community, clouds refer to condensates that grow from an atmospheric species when the partial pressure of the vapor exceeds its saturation vapor pressure (Marley et al. 2013). “Hazes” generally refer to particles produced from chemistry in the atmosphere that results in the formation of involatile solids. Hazes produced from photochemical reactions are called photochemical hazes. Photochemical haze formation is initiated by the production of haze precursors (radicals or ions) from the photolysis of simple molecules (CH_4 , N_2 , CO , SO_2 , ...). Neutral or ion chemistry results in the formation of macromolecules that will further grow to aerosols through coagulation and through chemistry.

Photochemical Hazes in the Solar System

Earth

On Earth, a stratospheric aerosol layer (called the Junge layer) is present between the tropopause and 30 km. It is sustained by natural emission of OCS and by volcanic injection of SO_2 , whose photolysis leads to the formation of sulfuric acid (H_2SO_4) aerosols.

In the troposphere over large cities, photochemical hazes called photochemical smog are produced by the photolysis of nitrogen oxides (NO and NO_2), which react with volatile organic compounds, forming organic aerosols. The combustion of fossil fuel is the main source of these nitrogen oxides and organic molecules. Photochemical smog represents a major health issue.

Despite these sources of photochemical hazes, Earth's atmosphere globally remains clear and haze-free. This is mostly due to the high fraction

of O_2 , which leads to the formation of OH radicals. The latter limit the formation of organic hazes by oxidizing organic molecules (e.g., CH_4). Before 2.4 Ga, Earth's atmosphere was much more reduced and O_2 was absent or just in very low amounts. Methane produced by methanogens may have reached high levels in the Archean atmosphere (3.8–2.5 Ga), potentially with a CH_4/CO_2 ratio exceeding 0.2. Under such conditions, photochemical models and lab experiments predict the formation of photochemical organic haze, similar as on Titan (Trainer et al. 2006). The early Earth, in particular at the end of the Archean, may have been covered by organic hazes (Zerkle et al. 2012).

Venus

Venus is covered by thick layers of sulfuric acid clouds and hazes. The photolysis of SO_2 in the upper atmosphere initiates chemical cycles which convert SO_2 into H_2SO_4 and S_8 . These compounds condensate into sulfuric acid and sulfur aerosols. Sulfuric acid aerosols above 60 km can be considered as photochemical haze, since they form from the recently photochemically produced H_2SO_4 . Aerosols below 60 km are considered as clouds since they form from the global and long-term tropospheric H_2SO_4 .

Titan

Titan is the archetype of hazy world. CH_4 and N_2 in Titan's upper atmosphere are photolyzed by UV photons or ionized by charged particles from Saturn's magnetosphere. The orbiter Cassini revealed the unexpected and fundamental role of ion-neutral chemistry leading to the formation of massive molecules, including benzene and polycyclic aromatic hydrocarbon, in Titan's ionosphere (Waite et al. 2007, Lavvas et al. 2013). Neutral chemistry initiated by photochemistry likely dominates the growth of particles below ~800 km. The large thermally driven pole-to-pole Hadley-like circulation, coupled with particle microphysics, produces a detached layer of haze particles above Titan's stratosphere (Rannou et al. 2002, Lavvas et al. 2009). The tropospheric methane cycle with cloud

condensation/precipitation tends to eliminate hazes, which deposit at the surface and may be the major constituent of Titan's dunes. Hazes also have a major impact on the radiative budget of Titan's atmosphere. Absorption of solar radiation by hazes produces a stratospheric thermal inversion and a cooling of the surface by an anti-greenhouse effect (McKay et al. 1991).

Pluto

The New Horizon probe revealed photochemical hazes in Pluto's atmosphere, similar as on Titan (Gladstone et al. 2016). These hazes are likely produced from the photolysis of CH_4 and N_2 by solar far-UV and with also a contribution from interplanetary Lyman- α emission. A difference compared with Titan is the larger abundance of atmospheric CO, which may change the composition and optical properties of hazes. Pluto's hazes dominate the atmospheric radiative balance from the ground to an altitude of 700 km (Zhang et al. 2017). They explain the observed thermal profile, colder than expected.

Giant Planets

All giant planets in the Solar System have hazes in their atmosphere. Their formation is likely initiated by UV photolysis and by energetic magnetospheric particles in the auroral regions. The high concentration of UV-absorbing hazes at high latitudes on Jupiter and Saturn suggests a primary formation by auroral energy deposition coupled with a confinement within the polar vortex.

Photochemical Hazes on Exoplanets

Most of exoplanets seem to be cloudy or hazy (Sing et al. 2016). Their presence is suggested by flat transit spectra with reduced molecular absorption bands and Mie slope in the visible. These are either condensate clouds or photochemical hazes. It is currently difficult to distinguish them and they represent a major issue for the characterization of exoplanetary atmospheres. Lab experiments suggest that photochemical hazes could form for a large range of temperature and atmospheric composition, but with significant variations in the production rate (Hörst et al.

2018). Hazes with sub-micrometric sizes (as on Titan) are expected to be optically thinner in the infrared. Future observations by JWST and ARIEL in the infrared may allow to characterize the optical properties of hazes and the chemical composition of hazy planets.

Astrobiological Interest

Lab experiments using plasma chambers or UV sources are particularly useful to understand the formation, composition, and properties of photochemical hazes. The particles produced by such experiments are called tholins. Analysis of tholins formed under Titan-like conditions revealed that they contain numerous prebiotic molecules, including amino acids and nucleotide bases (Hörst et al. 2012). The hydrolysis of tholins naturally released such prebiotic molecules (Poch et al. 2012). Photochemical organic hazes have therefore a major astrobiological interest and may have contributed to the prebiotic chemistry leading to life on Earth.

Definition

Photochemistry is defined as chemical processes initiated by photon-induced electronic excitation, not involving ionization. Energetic processing of interstellar ice mantles and planetary atmospheres via photochemistry is a critical mechanism in the extraterrestrial synthesis of prebiotic molecules. Molecular panspermia posits that space-synthesized prebiotic molecules (e.g., amino acids and sugars) were delivered to Earth by comets, kick-starting life.

Word range of Entry: approx. 2200 words excl. References, as agreed with the Editors-in-Chief

Overview

Photochemistry, which involves nonionizing radiation, is defined as “the branch of chemistry which relates to the interactions between matter and photons of visible (700–400 nm) or ultraviolet (UV-A region (400–315 nm), UV-B (315–280 nm), and UV-C (280–100 nm)) light and the subsequent physical and chemical processes which occur from the electronically excited state, formed by photon absorption” (Wardle 2009). According to a recent review, “Interstellar ice photochemistry is an efficient pathway to chemical complexity in space. It is a source of prebiotic amino acids and sugars, and maybe the original source of enantiomeric excess on the nascent Earth”(Öberg 2016). Condensed-phase photochemistry occurs not only on ice mantles of interstellar (sub)micron-size grains (Herbst 2017; Arumainayagam et al. 2019; Sandford et al. 2020), but also on ices of extrasolar and solar planets (e.g., Mars), dwarf planets (e.g., Pluto), moons (e.g., Europa), asteroids (e.g., Ceres), and comets (e.g., 67P/Churyumov–Gerasimenko). Gases surrounding these ices also undergo photochemistry, likely contributing to the synthesis of prebiotic molecules. Gas-phase photochemistry may also occur in circumstellar envelopes associated with the last phase of stellar evolution. Interestingly, the ultraviolet irradiation of interstellar ice analogs containing H₂O, CH₃OH, and NH₃ leads to the production of ribose, the central molecular subunit of RNA (Meinert et al. 2016). The idea that organic building blocks of life originate in outer space is the fundamental assumption of molecular panspermia, which posits that endogenous delivery of prebiotic molecules kick-started abiogenesis on Earth.

In contrast to thermal chemistry, which involves the ground electronic state, photochemistry concerns electronically excited states (Arumainayagam et al. 2021). The electronically excited molecule may decay via primary *photophysical* and/or *photochemical* processes such as (1) luminescence (fluorescence or phosphorescence): $A^* \rightarrow A + h\nu$, (2) radiationless decay: $A^* + M \rightarrow A + M^*$, (3) quenching: $A^* + B \rightarrow A + B$, (4) photodissociation: $A^* \rightarrow B + C$, (5) photoisomerization: $A^* \rightarrow B$, (6) electron transfer: $A^* + B \rightarrow A^+ + B^-$,

(7) excitation transfer or sensitization: $A^* + B \rightarrow A + B^*$, (8) bimolecular reaction: $A^* + B \rightarrow C + D$, (9) H-abstraction reaction: $A^* + RH \rightarrow AH + R$, and (10) ion-pair formation: $AB^* \rightarrow A^+ + B^-$. None of these processes involve the production of low-energy electrons, a signature characteristic of radiation chemistry. Reactions attributable solely to photochemistry are limited to those initiated by photons associated with far (deep)-UV (4.1–6.2 eV) (300–200 nm), near-UV (3.1–4.1 eV) (400–300 nm), and occasionally visible (1.8–3.1 eV) light. We focus on photodissociation to produce radicals because current astrochemical simulations do not invoke photosensitization, abstraction reactions, photoaddition, or photocyclization. Depending on the shape of the excited state potential energy curves, photodissociation of a diatomic molecule may occur via (1) a bound upper state, (2) an unbound upper state, (3) predissociation, (4) indirect photodissociation, or (5) spontaneous radiative dissociation (Arumainayagam et al. 2021). In addition to photochemistry, vacuum ultraviolet (VUV) (6.2–12.4 eV) and extreme ultraviolet (EUV) (10.0–124 eV) light may initiate radiation chemistry, which involves “chemical changes produced by the absorption of radiation of sufficiently high energy to produce ionization”(Woods 1998).

Several core principles govern photochemistry (Arumainayagam et al. 2021). According to the Grotthuss-Draper law of photochemistry, only the light absorbed is effective in promoting photochemistry. This law may appear self-evident, but note that in stimulated emission, a molecule emits radiation that it had not previously absorbed. Most photochemical reactions obey the Bunsen-Roscoe law, according to which a photochemical effect is directly proportional to the total energy dose, irrespective of the time required to deliver that dose. This law may not apply to high photon flux experiments involving multiphoton processes. In other words, photochemical effects, in contrast to some radiation chemistry outcomes, depend on the photon fluence (photons per unit area, integrated over time) but not on the flux (photons per unit area per unit time). The Bunsen-Roscoe law is assumed valid for ice processing when extrapolating laboratory simulations (flux $\sim 10^{14}$ photons/cm²/sec) to dark, dense

molecular clouds (flux $\sim 10^4$ photons/cm²/sec). According to the Stark-Einstein law, a single molecule absorbs only one photon in the primary step of a photochemical reaction. Multiphoton processes typically occur in laboratory settings involving lasers with high incident photon fluxes (Arumainayagam et al. 2021).

Electronic excitation ($A + h\nu \rightarrow A^*$), the fundamental first step in photochemistry, is governed by spin and electric dipole transition selection rules, the latter of which are obtained from group theory symmetry arguments (Arumainayagam et al. 2021). The selection rules given below are best defined for gas-phase species. Strongly allowed transitions for gaseous diatomic molecules depend upon the couplings among different angular momentum quantum numbers and whether the quantization is best treated in space-fixed or molecule-fixed coordinates. For the so-called pure Hund's case (a), transitions of linear molecules involve the following restrictions on angular momentum quantum numbers: (1) $\Delta A = 0, \pm 1$ (A is the quantum number that specifies the total electronic orbital angular momentum along the molecular z-axis); (2) $\Delta S = 0$ (S is the total spin angular momentum); and (3) $\Delta Q = 0, \pm 1$ (Q is the quantum number that specifies the total orbital angular momentum along the molecular z-axis). Electronic transitions in diatomic molecules are subject to additional restrictions resulting from their high degree of symmetry, as detailed elsewhere (Atkins and Friedman 2011; Bernath 2015). In molecular orbital parlance, $\sigma^* \leftarrow \sigma$ and $\pi^* \leftarrow \pi$ transitions are allowed but not $\pi^* \leftarrow \sigma$ or $\sigma^* \leftarrow \pi$. While the typical cross section for allowed electronic transitions is 10^{-17} – 10^{-18} cm², the nominally forbidden $\pi^* \leftarrow n$ transitions, involving excitation of non-bonding electrons to π^* orbitals in species such as carbonyls, have significantly lower cross sections. Solvent interactions cause $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ transitions to “redshift” and “blueshift,” respectively (Arumainayagam et al. 2021).

In the gas phase, photon-induced processes are said to be spin-allowed when the spin multiplicity does not change (e.g., singlet to singlet and triplet to triplet transitions) (Arumainayagam et al. 2021). For example, photon-induced gas-phase

reactions of ammonia include spin-allowed (e.g., $\text{NH}_3 + h\nu \rightarrow \text{NH}(a^1\Delta) + \text{H}_2$) and disallowed (e.g., $\text{NH}_3 + h\nu \rightarrow \text{NH}(X^3\Sigma^-) + \text{H}_2$) processes. Because spin-orbit coupling is proportional to the fourth power of the atomic number, spin-forbidden transitions (e.g., singlet to triplet) become more likely for metal-containing heavy molecules in which the spin and orbital angular momenta are more strongly coupled. In contrast to the gas phase, spin-forbidden photon-induced transitions are allowed in the condensed phase (Bondybey et al. 1996).

Photochemistry in the condensed phase may differ from that in the gas phase because the collective behavior of molecules in close proximity influences the absorption process and the fate of the excited species (Arumainayagam et al. 2021). Because solvation reduces electronic state energies by different amounts, the absorption spectrum changes, causing spectra to be typically blue-shifted in the condensed phase. The solid O₂ absorption band, which peaks at ~ 7.0 eV, is attributed to the absorption of the (O₂)₂ dimer (Mason et al. 2006). This phenomenon is exclusive to the condensed phase. Absorption intensities may also change because interaction with neighboring molecules invalidates selection rules. In addition, quenching/collisional deactivation of the electronically excited state in the condensed phase is more likely than in the gas phase (Arumainayagam et al. 2021). Photochemistry yields in the condensed phase are diminished because of the so-called “cage effect,” which allows two photofragments of a molecule to be trapped and undergo numerous collisions before escaping the cage (Arumainayagam et al. 2021). Condensed-phase photochemistry is influenced by the formation of excitons, which are localized electronically excited states associated with generating a negative electron and a positive hole (absence of an electron in the valence band) bound by Coulombic attraction (Arumainayagam et al. 2021). In contrast to gas-phase photochemistry, condensed-phase photochemistry may be altered by the formation of supra-molecular excited collisional complexes (e.g., excimers (**excited dimer**) or exciplexes (**excited complexes**)) whose lifetime is longer than those of the corresponding ground-state complexes (Arumainayagam et al. 2021).

Photochemistry in space is initiated by three nonionizing (typically <10 eV) photon sources (Arumainayagam et al. 2021): (1) the interstellar radiation field (ISRF), permeating all of space except within dark, dense molecular clouds, plays a vital role in the photochemistry occurring in the outer layers of interstellar clouds, protoplanetary disks, and circumstellar envelopes (extended atmospheres of older stars, such as asymptotic giant branch (AGB) stars), (2) protostellar (stars in the act of formation before the so-called main sequence of hydrogen burning in their interiors) and stellar blackbody radiation lead to photochemistry in protoplanetary disks and planetary objects, and (3) secondary UV radiation, produced by primary cosmic rays exciting the Lyman and Werner band systems of molecular hydrogen, initiates chemical reactions within cold starless cores.

Photochemistry in the gas phase occurs in the following extraterrestrial locations (Arumainayagam et al. 2021):

1. Protoplanetary disks (e.g., the production of cyanides has been attributed to the interaction of UV light hydrogen cyanide (HCN) (Du et al. 2015).
2. Planets (e.g., photochemistry of methane likely occurs in Mars' atmosphere (Taysum and Palmer 2020))
3. Moons (e.g., photodissociation of N_2 in Titan's atmosphere leads to the production of nitriles (Iino et al. 2020) and vinyl cyanide, a potential precursor of cell membranes/vesicle structures (Palmer et al. 2017).
4. Circumstellar envelopes (e.g., photochemistry in these planetary nebulae (when these objects were first discovered in 1784, they were mistakenly associated with planets) facilitates the production of complex molecules that possibly include polycyclic aromatic hydrocarbons (PAHs consist of concatenated aromatic rings) (Zhen et al. 2018), which may provide ingredients for a new stellar cycle)

Gas-phase photochemistry is studied using techniques such as flash photolysis, microwave

discharge flows, mass spectrometry, synchrotron radiation, plasma dissociation, Laval expansion, crossed molecular beam techniques, velocity map imaging, and computational chemistry (Arumainayagam et al. 2021).

Condensed-phase photochemistry by UV light leading to the production of radicals is one of five postulated mechanisms (Fig. 1) for the processing of interstellar ~ 0.01 μm -thick ice mantles surrounding the micron-sized dust grains found in dark, dense molecular clouds (Arumainayagam et al. 2021). The photochemistry induced by UV light produces both light and heavy radicals. While facile light radical diffusion is possible at ~ 10 K (Oba et al. 2018), (possibly leading to the atom addition chemistry shown in Fig. 1), the gradual warm-up from ~ 10 K in cold cores to ~ 100 K in hot cores/hot corinos allows for heavy radical diffusion (Arumainayagam et al. 2021). The subsequent barrierless radical-radical reactions produce complex organic molecules (COMs), which likely lead to the synthesis of precursors of biologically relevant molecules. Condensed-phase photochemistry may also occur in protoplanetary disks, the planetary birthplaces that evolve from hot cores/corinos (Arumainayagam et al. 2021). Another example of condensed-phase photochemistry is chemical synthesis in the icy bodies of the outer solar system initiated by solar photons (Kulikov et al. 2019). For example, solar photons are thought to contribute to the condensed-phase synthesis of tholins, the hydrolysis of which may lead to the production of amino acids and nucleobases on Pluto (Cruikshank et al. 2019).

Energetic processing of cosmic ices via photochemistry is thought to be a dominant mechanism for the extraterrestrial synthesis of prebiotic molecules (Arumainayagam et al. 2021). According to a 2019 PNAS publication, "Meteorites were carriers of prebiotic organic molecules to the early Earth; thus, the detection of extraterrestrial sugars in meteorites implies the possibility that extraterrestrial sugars may have contributed to forming functional biopolymers like RNA" (Furukawa et al. 2019).

Basic Methodology

Surface science techniques are typically used to analyze condensed-phase photochemistry relevant to astrobiology. Such experiments are usually conducted using nanoscale thin films of multilayer adsorbates under ultrahigh vacuum (UHV) conditions ($P \sim 10^{-9}$ torr). Photon-stimulated desorption (PSD) experiments, conducted *during* irradiation, have yielded vital information relevant to initial photon-induced processes. In addition, analyzing the products *following* < 10 eV photon irradiation has provided new insights into photochemistry. The surface science techniques temperature-programmed desorption (TPD), reflection absorption infrared spectroscopy (RAIRS), X-ray photoelectron spectroscopy (XPS), and high-resolution electron energy loss spectroscopy (HREELS) are particularly useful for postirradiation analysis. Microwave-discharge

hydrogen-flow lamps (MDHLs) used in “photochemistry” experiments typically initiate both photochemistry and radiation chemistry in cosmic ice analogs. In contrast to MDHL sources, irradiation with deuterium lamps (3.1–7.8 eV), tungsten halogen lamps (1.1–3.9 eV), or xenon arc lamps (0.5–6.2 eV) typically induces only photochemistry. Laser sources can generate tunable coherent narrow-bandwidth UV radiation by employing resonant four-wave mixing. Synchrotron radiation sources (e.g., NSRRC in Taiwan, DESIRS beamline at SOLEIL in France) produce continuous intense photon emission.

Key Research Findings

1. Photochemistry of (a) interstellar ices, near star-forming regions, likely leads to the extra-terrestrial synthesis of prebiotic molecules.

2. Because the ionization threshold is lower in the condensed phase than in the gas phase, most “photochemistry” studies of astrochemistry likely involve radiation chemistry.

Future Directions

The newly deployed James Webb Space Telescope (JWST) should provide new insights into the mechanisms (e.g., photochemistry) responsible for the extraterrestrial synthesis of prebiotic molecules. There is a critical need for more wavelength-dependent condensed-phase astrochemically relevant photochemistry studies, of which there have been only a few.

Definition

Atmospheric photochemistry is the study of light initiated chemical reactions which occur in the atmospheres of planetary bodies. These reactions play an important role in climate, and likely contributed to prebiotic organic synthesis.

Overview

Planetary atmospheric photochemistry occurs when incident radiation contains enough energy to dissociate bonds within the atmospheric molecules. Bond energies in atmospheric molecules are on the order of 10^2 – 10^3 kJ mol⁻¹, and thus bond dissociation requires photons in the ultraviolet and visible region of the electromagnetic spectrum. A photochemical reaction occurs when the absorption of light triggers an electronic transition within the molecule, activating the reaction. Products of photo dissociation are typically highly reactive radicals.

A photochemical reaction is represented by the following general equation:

where $h\nu$ represents the energy of the photon. This reaction is characterized by a first-order rate

constant (known as a “J-value”), and the rate of photochemical dissociation is expressed as:

$$\text{Rate (molecules cm}^{-3}\text{s}^{-1}) = -J(AB).$$

The J-value is dependent upon the absorption spectrum of the molecule, the available light in the atmosphere, and the quantum yield for dissociation once the molecule is electronically excited by light absorption. The quantum yield is the ratio of the number of molecules dissociated to the number of photons absorbed, a dimensionless parameter ranging from 0 to 1. The lifetime (τ) of a particular molecule with respect to photolysis loss is given by $1/J$, and this value allows for comparison between photolysis and other possible loss processes, such as transport.

To calculate a J-value at any point in the atmosphere for any particular molecule, the following summation is used over the wavelength (λ) range of interest:

$$J \text{ (s}^{-1}) = \sum_{\lambda} I(\lambda) \sigma(\lambda) \varphi(\lambda) d\lambda$$

where $I(\lambda)$ is the available light (photons cm⁻² s⁻¹), $\sigma(\lambda)$ is the absorption cross section of the molecule (cm² molecule⁻¹), and $\varphi(\lambda)$ is the quantum yield. The photon flux is a property of the planet, determined by the incident angle of sunlight, flux at the top of the atmosphere, and the amount of light absorbed above the point of interest. Both the absorption cross section and quantum yield are properties of the molecule.

The dependence on the photon flux leads to a strong dependence on altitude, which contributes to the vertical distribution of gases within an atmosphere and serves to attenuate the light that reaches the planet's surface. Figure 1 shows the penetration depth of ultraviolet solar radiation into the Earth's atmosphere and relevant absorbing molecules. On Earth, the highest energy ultraviolet radiation is effectively absorbed by O₂ and O₃ before reaching the surface, protecting life from this damaging radiation.

Atmospheric photochemistry on the current Earth, early Earth, and other planets is of interest because of the effects photochemical processes can have on planetary environments. These

Photochemistry, Atmospheric,

Fig. 1 Depth of penetration of ultraviolet radiation in the Earth's atmosphere. The altitudes correspond to an attenuation of $1/e$. The principle absorbers are indicated. (Adapted from Brasseur and Solomon 2005)

include the chemical composition of the atmosphere, the attenuation of sunlight reaching the surface, the radiative balance of the planet, the oxidative capacity of the atmosphere, the production and delivery of organic molecules to the surface, and the generation of radiatively shielding hazes and pollution.

Definition

A photodesorption event occurs when the absorption of a UV (or X-ray) photon by a molecule condensed on a surface results in its desorption (direct photodesorption), in the “kick-out” of a nearby molecule (indirect photodesorption), or in dissociation followed by recombination and desorption (photochemical desorption). In space, photodesorption can regulate the locations of “snow-lines,” the transition regions where the dominant phase of volatiles changes from gas to ice (particularly in protoplanetary disks). Photodesorption from ices and other surfaces that mimic interstellar grain compositions is characterized experimentally to determine molecule-specific desorption efficiencies and mechanisms.

Overview

In dense and cold regions in space, atoms and molecules freeze out on interstellar grains, forming icy mantles that continue to evolve chemically. Photodesorption connects the surface/ice chemistry with the gas phase in regions that are too cold for efficient thermal ice evaporation. In

the presence of strong radiation fields, photodesorption will affect the location of “snowlines,” i.e., the molecule-specific transition regions where ice desorption overtakes freeze-out. In less exposed regions, where the ice phase dominates, low-level photodesorption can maintain a small fraction of molecules in the gas phase. This is important because it potentially enables the use of gas-phase spectroscopic observations as a probe of ice compositions.

Ice photodesorption efficiencies are measured experimentally in ultrahigh vacuum chambers, where interstellar ice equivalents are irradiated with broadband or monochromatic UV/X-ray sources and desorption rates are measured using a quartz balance, infrared spectroscopy, or mass spectrometry, or a combination of two or more of these techniques. These experiments can also be used to characterize the desorption process based on how the photodesorption rate responds to radiation at different fluxes and frequencies, and based on the effects of ice thickness, temperature, and morphology on the desorption efficiency. Experiments on photodesorption off metal surfaces have a long history (Avouris and Walkup 1989), while investigations of ice photodesorption date back to the mid-1990s (Westley et al. 1995).

Measured far-UV photodesorption efficiencies are high for some small molecules such as CO, N₂, O₂, CH₄, and CO₂, of the order 10⁻²–10⁻³ desorbed molecules per incident UV photon, somewhat lower for water ice, and substantial lower for most organic ices, including CH₃OH and CH₃CN (Öberg et al. 2009a, b; Bertin et al. 2012; Zhen and Linnartz 2014; Cruz-Diaz et al. 2016; Dupuy et al. 2017; Cruz-Diaz et al. 2018; Basalgète et al. 2021b; Fillion et al. 2021). Derived desorption mechanisms are ice specific. Simple ices that only present nondissociative excitations mainly desorb through the excitation of a subsurface molecule, followed by the kick-out of a surface molecule. CO and N₂ are in this category when exposed to a typical interstellar radiation field (Bertin et al. 2012). In contrast, many other astrophysically important ices, including O₂, H₂O, and CO₂, and most organic ices, only

have strong dissociative transitions in the far-UV and photodesorption proceeds differently: Following absorption of a photon, the dissociation fragments either desorb directly or recombine and desorb, or kick out a surface molecule (Andersson and van Dishoeck 2008; Hama et al. 2010). The number of active layers is generally larger for dissociative photodesorption because of the dynamics involved.

Extreme UV and X-ray photons may ionize as well as dissociate molecules resulting in the photodesorption of molecular ions. X-ray photodesorption efficiencies are generally less well constrained than far-UV photodesorption efficiencies, but there is some experimental evidence that they may be important for desorbing organic ices in star- and planet-forming environments (Andrade et al. 2010; Dupuy et al. 2018; Basalgète et al. 2021a).

Photodesorption efficiencies are included in astrochemical models of clouds, protostars, and protoplanetary disks to determine the division of molecules between the gas phase and the grain surfaces. Since the gas phase and grain surface chemical reactions are different, this is important to predict the chemical evolution during most stages of star and planet formation.

[PDR](#); [Photon dominated region](#)

Definition

A photodissociation region (PDR) is an interstellar gas phase in which far-ultraviolet (FUV; $6\text{ eV} < h\nu < 13.6\text{ eV}$, where eV is the energy of the radiation in electron volts) radiation plays a role in the heating and/or chemistry (Tielens and Hollenbach 1985a). These regions include the diffuse atomic ► [interstellar medium](#), and the surfaces of interstellar molecular clouds exposed to the interstellar radiation field and to intense radiation from nearby OB stars. Note that in the following article we use the standard astronomical

notation of square brackets (e.g., [CII]) indicating “forbidden” transitions, that is, transitions from a metastable state. Likewise, the ionization state of an atom is indicated by a Roman numeral, so that I indicates the neutral atom, II is once ionized, and so on (e.g., HII for ionized hydrogen).

Overview

The FUV range of energies is responsible for dissociating molecules and dominates the heating process in photodissociation regions (PDRs). The upper bound of this range is the energy required to ionize hydrogen, and thus PDRs are neutral hydrogen regions (in contrast, astronomers refer to plasmas of electrons and ionized hydrogen as ► [HII regions](#)). The FUV field is often measured in units of the Draine (Draine 1978) interstellar radiation field, equal to ~ 1.7 times the Habing (Habing 1968) local interstellar FUV field ($1.6 \times 10^{-3}\text{ erg cm}^{-2}\text{ s}^{-1}$ or $\sim 10^8\text{ photons cm}^{-2}\text{ s}^{-1}$). A common notation is that G_0 is the radiation field in units of the Habing field, and field strengths that are typically encountered range between $G_0 \sim 1.7$ for the interstellar field and $G_0 \sim 10^5$ for the Orion nebular PDR.

PDRs are found where FUV radiation from OB stars or the general interstellar radiation field shines on molecular clouds. The FUV radiation can affect the chemistry for visual extinctions up to $A_V \sim 8$ by maintaining in atomic form that oxygen that is not tied up in CO. The relation between extinction and hydrogen nucleus ► [column density](#) is $N = 1.9 \times 10^{21} A_V / Z' \text{ cm}^{-2}$ where Z' is the dust abundance relative to the abundance in the local galaxy. The mean extinction in giant ► [molecular clouds](#) is also $A_V \sim 8$ (Solomon et al. 1987), so much of the mass in molecular gas is in PDRs. PDRs are also found in the diffuse medium in cold ($T \sim 100\text{ K}$) and warm ($T \sim 8000\text{ K}$) neutral hydrogen clouds (see ► [Interstellar Medium](#)). The same physics that applies in the molecular cloud surfaces (Kaufman et al. 2006; Abel et al. 2005; Le Petit et al. 2006) also applies in the diffuse atomic interstellar medium (Wolfire et al. 2003; Shaw et al. 2006; Wolfire et al. 2008) but with weaker FUV field ($G_0 \sim 1\text{--}10$) and lower

hydrogen nucleus column densities ($N \sim 10^{19} - 10^{21} \text{ cm}^{-2}$). PDRs are also present in the neutral interstellar medium in starburst galaxies (Kaufman et al. 1999) and in galaxies with active galactic nuclei (Meijerink et al. 2007).

Structure

A PDR can be divided into various chemical regimes as a function of ► [optical depth](#) from the cloud surface (Sternberg and Dalgarno 1995). In the outer portions, the gas is mainly neutral atomic H, He, O, and C^+ (see Fig. 1, where ISRF is the interstellar radiation field and transition regions are indicated in color). Incident FUV radiation is absorbed by dust and large carbon molecules – ► [polycyclic aromatic hydrocarbons](#) (PAHs) – and mostly results in excitation of PAHs and grain heating. However, as much as 0.1–1% of the absorbed FUV is converted to energetic photoelectrons that are ejected from PAHs and grains and heat the gas. The gas generally attains a higher temperature ($T \sim 100\text{--}5000 \text{ K}$) than the grains ($T \sim 10\text{--}50 \text{ K}$) because of the much less effective cooling of the gas (predominantly via $[\text{CII}] 158 \mu\text{m}$ and $[\text{OI}] 63 \mu\text{m}$ ► [line emission](#)) relative to the dust continuum cooling. On the surfaces of molecular clouds, the warm gas leads to intense emission of the $[\text{CII}] 158 \mu\text{m}$ line and the $[\text{OI}] 63$ and $145 \mu\text{m}$ lines, as well as infrared (IR) dust continuum and near-infrared emission features (at 3.3, 6.2, 7.7, 8.6, and $11.3 \mu\text{m}$) believed to arise from PAHs.

Additional diagnostic line emission is provided by $[\text{SiII}] 35 \mu\text{m}$ and $[\text{FeII}] 26 \mu\text{m}$ (Si^+ and Fe^+), which can be used to estimate elemental abundances (Kaufman et al. 2006).

At extinctions $A_V > 1$ atomic hydrogen is converted to molecular hydrogen on grain surfaces and molecular H_2 vibrational transitions are produced. The grain photoelectric heating process still dominates, balanced by C^+ and O^0 fine-structure line cooling. In this region, the gas is mainly H_2 , but the carbon is in the form of C^+ and not CO. Since CO is often used as a tracer of molecular gas, this regime has been called “dark gas” (i.e., no CO emission; Grenier et al. 2005; Wolfire et al. 2010; this has nothing to do with dark matter or dark energy). The dark gas may increase the molecular mass of galactic clouds by $\sim 30\%$ relative to estimates based on the CO emission alone and could increase the molecular mass by a factor of ~ 30 in low-metallicity (low abundance of elements heavier than helium) galaxies such as the Small Magellanic Cloud (Leroy et al. 2007). Deeper in PDRs ($A_V > 2\text{--}3$), the transition of C^+ to C to CO occurs, and the CO rotational and $[\text{CI}] 370$ and $609 \mu\text{m}$ lines originate. In the deepest layers, grain photoelectric heating or cosmic-ray heating dominates depending on the strength of the incident field, balanced by cooling from rotational transitions of CO. The chemistry of oxygen and carbon not locked in CO is affected by the FUV radiation to cloud depths of $A_V \sim 5\text{--}10$.

Photodissociation

Region, Fig. 1 Typical structure of PDR chemical zones as a function of extinction A_V into a cloud illuminated by an FUV radiation field

Heating

Detailed investigations of the grain photoelectric heating process have been presented by Bakes and Tielens (1994) and Weingartner and Draine (2001). An FUV photon is absorbed by a dust grain that can eject a hot electron into the gas. The electron kinetic energy is a function of the accumulated charge on the grain since the electron must overcome the Coulomb barrier of the accumulated charges. The grain charge is found by balancing the ► [photoionization](#) rate with the recombination rate. The calculated heating efficiency from Bakes and Tielens (1994) is shown in Fig. 2.

Figure 2 shows that as grains become positively charged and hence the electron density n_e in the gas increases, the heating efficiency drops. For typical conditions in the neutral diffuse ISM (Wolfire et al. 2003) ($G_0 \sim 1.7$, $n_e/n \sim 1.6 \times 10^{-4}$, $n \sim 30 \text{ cm}^{-3}$, $T \sim 85 \text{ K}$, where n is the hydrogen nucleus volume density; i.e., n includes both atomic and molecular hydrogen), grains are mainly neutral, and the photoelectric heating efficiency is near maximum. In contrast, for the photodissociation region in Orion (Tielens and Hollenbach 1985b) ($n \sim 2 \times 10^5 \text{ cm}^{-3}$, $G_0 \sim 1 \times 10^5$, and $T \sim 550 \text{ K}$), grains are highly charged, and the heating efficiency is a factor of 10 lower.

Note, however, that the efficiency shown in Fig. 2 is integrated over the grain size distribution from large grains, $\sim 0.1 \text{ }\mu\text{m}$, to large molecules,

$\sim 5 \text{ }\text{\AA}$, with a distribution in radius $n(a) \propto a^{-3.5}$. Bakes and Tielens (1994) found that $\sim 1/2$ of the heating comes from the smallest grain sizes. The efficient heating from small grains is mainly for two reasons. First, the yield increases as the grain size decreases. The yield is the fraction of electrons that reach the grain surface that are ejected from the grain. In a large grain, the electron energy is lost to infrared continuum radiation, but in a small grain, a greater fraction can reach the surface to be ejected.

Second, the ionization-to-recombination ratio is proportional to a^2 so that larger grains become charged and their heating efficiency drops. The smallest population of grains is almost certainly PAHs (polycyclic aromatic hydrocarbons; Allamandola et al. 1985; Leger and Puget 1984). The simplest PAH is benzene with six carbon atoms in a ring; larger PAHs are composed of multiple rings.

In addition to photoelectric heating from grains, various other heating processes could contribute depending on the incident field strength and depth into the cloud. At large ► [optical depth](#), heating from cosmic-ray ionization could become important. The primary ionization rate per hydrogen nucleus is approximately $\zeta_{\text{xp}} \sim 1.8 \times 10^{-17} \text{ s}^{-1}$ with each ionization producing a primary electron of mean energy 35 eV. The primary electrons can produce secondary ionizations, molecular dissociation, atomic and molecular excitation, or gas

Photodissociation

Region, Fig. 2 Grain photoelectric heating efficiency from Bakes and Tielens (1994), where T is temperature, n_e is electron density and G_0 measures the radiation field (see text)

heating, with yields depending on the electron and molecular abundances (Dalgarno et al. 1999). Additional heating processes at large optical depth may include IR dust continuum pumping of [OI] 63 μm followed by collisional de-excitation and gas-dust interactions (Tielens and Hollenbach 1985a).

At small $\blacktriangleright$ **optical depth**, the heating is dominated by grain photoelectric heating, while photoionization of CI and photodissociation of H_2 contributes about 1% to the heating (Tielens and Hollenbach 1985a).

Cooling

At $A_V < 3$, the gas cools mainly by collisional excitation by H and H_2 of fine-structure transitions, followed by radiative de-excitation. Dominant cooling lines include [CII] 158 μm , [OI] 63 μm , and [CI] 610 μm . Along with the cooling transitions, weaker lines can be used as diagnostics of the gas density, temperature, and incident FUV fields. These include [OI] 145 μm , [CI] 370 μm , [SiII] 35 μm , [FeII] 26 μm , and the H_2 rotational transitions 0–0 S (0) 28 μm , 0–0 S(1) 17 μm , and 0–0 S(2) 12 μm . Deeper into the cloud, CO rotational transitions dominate the gas cooling.

Chemistry

Formation and Destruction of H_2

In steady state, photodissociation of molecular hydrogen is balanced by formation on dust grains. An H_2 molecule in the ground state can absorb a FUV photon ($\lambda < 1108 \text{ \AA}$) and be excited to the first or second electronic level. About 10% of the pumped molecules de-excite to the vibrational continuum thereby dissociating the molecule. The remainder land in bound excited states resulting in a UV emission line and an IR vibrational cascade. PDR computational codes have been constructed including detailed H_2 models that account for self-shielding in individual pumping lines as well as the infrared line emission produced in the fluorescent cascade (Draine and Bertoldi 1996; Sternberg and Dalgarno 1989; Black and van Dishoeck 1987). For $G_0/n < 0.025$, H_2 self-shielding dominates over dust shielding, and the H/H_2 transition is drawn to the cloud surface (Burton et al. 1990).

Formation and Destruction of CO

The formation of CO follows that of H_2 and OH as one goes deeper into the cloud. In the gas phase, the formation of OH is initiated by the cosmic-ray ionization of H_2 (van Dishoeck and Black 1986; see also $\blacktriangleright$ **Interstellar Chemical Processes**). Reactions with H_2 and O lead to

Dissociative recombination of H_3O^+ leads directly to OH or to H_2O (which is then photodissociated to form OH).

Hollenbach et al. (2009) has suggested that for typical cosmic-ray ionization rates, formation of OH on grain surfaces can exceed the gas phase production. In this case, the OH abundance is determined by equating the formation of OH on grain surfaces

to the FUV photodissociation of OH

where $h\nu$ represents a photon.

Once OH is formed, the chemistry proceeds as follows (van Dishoeck and Black 1988):

The first reaction dominates the formation of CO^+ ; the second reaction dominates the destruction of CO^+ and the formation of HCO^+ ; the third reaction dominates the destruction of HCO^+ and

the formation of CO; the last reaction dominates the destruction of CO. As a result, every CO^+ that is formed by the first reaction results in a formation of a CO by the third reaction. The H_2 absorption lines in the FUV overlap with several of the CO dissociating transitions, and thus the H_2 can shield the CO at larger optical depth. The shielding factor is tabulated for a range of H_2 and CO columns in Visser et al. (2009). An expression for the depth at which the CO ($J = 1-0$) line becomes optically thick, $N(\text{CO}) \sim 2 \times 10^{16} \text{ cm}^{-2}$, is given by Wolfire et al. (2010).

Since the heating rates and the depth to the transition regions depend on G_0/n , we expect regions with the same ratio of G_0/n to have similar structure.

Electron Abundance

The electron abundance is important in setting the grain photoelectric heating rate and in setting the abundance of various atomic and molecular ions that are neutralized or destroyed by recombination. At low A_V ($<2-3$), electrons are mainly provided by the photoionization of C to C^+ and by photoionization of He by soft X-rays. Essentially, all the C is in the form of C^+ yielding an electron abundance $n_e/n \sim n_{\text{C}^+}/n \sim 1.6 \times 10^{-4}$, the value of the gas phase carbon abundance in the ► [interstellar medium](#) (Sofia et al. 2004). The charge exchange of metal cations with PAH—can effectively compete with gas phase recombination, and the inclusion of PAHs in the chemical network can significantly decrease the optical depth to the C^+/C transition and increase the neutral abundances of species such as C^0 , Si^0 , Mg^0 , Fe^0 , and S^0 (Wolfire et al. 2008; Bakes and Tielens 1998). Deeper into the cloud, electrons are provided mainly by cosmic-ray ionization of H and He.

Model Example

A sample model calculation is presented in Wolfire et al. (2010).

Observations

The bright HII region M17 and associated PDR are shown in Fig. 3. The image is taken with the

Spitzer IRAC instrument and is dominated by PAH emission. The PAH emission lies between the ionized gas at the center and molecular gas to the upper left and right. Shown in Fig. 4 is a strip map in [CII] $158 \mu\text{m}$ emission taken along the line shown in Fig. 3. The [CII] line emission peaks at the PDR but also seems to have a tail of emission in the molecular gas, perhaps indicating FUV penetration in a clumpy medium. We also show in Fig. 5 a Spitzer IRS spectrum near the ionized/neutral interface showing bright PAH emission but also H_2 pure rotational lines and fine-structure lines from ionized gas.

Future Directions

The basic PDR model seems to provide good fits to many observations, especially for bright PDRs. There are, however, a few emerging problems in which more detailed modeling is required or laboratory measurements are needed to constrain the theory.

Turbulence

We know that atomic and molecular clouds are turbulent with a log-normal probability density distribution (Goodman et al. 2009; Vazquez-Semadeni 1994). The chemical rates are proportional to the gas density squared, and thus the rates can be quite different in the extreme densities. In general, the dynamic time to transport molecular material out of the cloud interior to the atomic surface, or to transport atomic material from the surface inward, is longer than the chemical equilibrium times (Wolfire et al. 2010), but there are cases for low G_0 or strong H_2 self-shielding when the time-dependent chemistry can be important (Glover and Mac Low 2007). An additional problem is that the FUV penetration depends on column density that can be different in the high-density and low-density regions. Some initial work has been done to investigate turbulent PDRs, but much more can be done in the areas of time-dependent chemistry, turbulent structure, and line emission.

Photodissociation

Region, Fig. 3 Spitzer IRAC observations of the M17 HII region and PDR. The *green line* is about 10 arcmin in length and crosses the M17SW PDR, and shows the direction of the [CII] strip map shown in Fig. 4. The *box* shows the location of the Spitzer IRS spectrum shown in Fig. 5

Photodissociation

Photodissociation

Region, Fig. 5 Spitzer IRS observations of the PDR M17SW showing flux versus wavelength, from Povich et al. (2007). Vertical solid lines show the location of the PAH features

XDRs

Another type of region that is of increasing importance is called an XDR (Meijerink et al. 2007), in which hard X-ray radiation ($h\nu > 1$ keV) dominates the heating and chemistry. The most luminous XDRs are associated with black holes in galactic nuclei in which the X-ray emission penetrates the surrounding molecular clouds. XDRs are expected to have large hydrogen nucleus column densities ($N > 10^{22}$ cm $^{-2}$) and high volume densities ($n > 10^5$ cm $^{-3}$), and we expect to see highly excited molecules such as CO with rotational transitions up to $J = 30$ – 29 (~ 87 μ m; Spaans and Meijerink 2008). Spectrometers on board Herschel and the aircraft SOFIA will open new spectral windows in order to observe the highly excited molecular gas in XDRs.

Photoevaporation of Protoplanetary Disks

Steven B. Charnley

Solar System Exploration Division, Code 691, Astrochemistry Laboratory, NASA Goddard Space Flight Center, Greenbelt, MD, USA

Definition

The physical process in which radiation from a young ► [protostar](#) causes the removal of gas from its circumstellar disk is called photoevaporation. Energetic stellar radiation, comprising mainly extreme ultraviolet (EUV; wavelengths from 121 nm down to 10 nm) and far ultraviolet (FUV; 200–122 nm) photons and X-rays, heats the surface layers of the gaseous disk, producing thermal pressure gradients that permit the gas to escape the gravitational potential of the disk in an expanding ► [hydrodynamic flow](#).

Anoxygenic phototrophic Fe(II) oxidation

Chemical Formula

Definition

The process by which photosynthetic microorganisms fix CO_2 into organic matter using light as an energy source and reduced iron, Fe(II), as a source of electrons.

History

The existence of microbes which could conduct photoferrotrophy was first proposed almost a decade before any bacteria capable of this metabolism were discovered. Hartman (1984) had looked at Archean and Proterozoic banded iron formations which were previously proposed to have formed when oxygen produced by cyanobacteria reacted with reduced iron (Fe(II)) in the Earth's early, oxygen-poor, ferruginous oceans (Cloud 1973). He suggested instead that these deposits were formed by photosynthetic microorganisms which harvested energy by anaerobic photosynthesis, and could use the abundant Fe(II) in the anoxic oceans as an electron donor. This process would provide a mechanism by which Fe(II) could be oxidized and Fe(III) oxyhydroxide minerals precipitated even in the absence of oxygen. Nine years later, the first anoxygenic phototrophic Fe(II)-oxidizing bacteria were discovered (Widdel et al. 1993).

Overview

It is now well accepted that photoferrotrophs could have dominated the Earth's oceans prior to the oxygenation of the atmosphere (Kappler et al.

2005), and they are still widespread in anoxic aquatic and terrestrial habitats today. Most photoferrotrophs isolated so far come from marine or freshwater sediments, or small terrestrial aquatic habitats such as iron-rich ditches or streams. They are typically of low abundance in sediments, probably due to limitations imposed by their requirement for light (Laufer et al. 2016). They can make significant contributions to Fe(II) oxidation in the anoxic and ferruginous water column of stratified lakes. For example a photoferrotroph was enriched from the water column of ferruginous Lake La Cruz in Spain and shown to contribute to Fe(II) oxidation in situ (Walter et al. 2014). Even when iron(II) is low, photoferrotrophs can still have a significant effect on the biogeochemistry of stratified lakes due to rapid recycling of Fe(II) by Fe(III) reduction in a so-called cryptic cycle. For example, they are thought to account for up to 10% of total carbon fixation in Lake Cadagno which is meromictic but low in iron due to rapid re-cycling between microbial Fe(II) oxidation and microbial Fe(III) reduction (Berg et al. 2016). Despite their apparent importance in these stratified lakes, *Chlorobium phaeoferrooxidans* which was isolated from Lake Kivu in East Africa, is currently the only isolate to originate from a ferruginous water column (Crowe et al. 2017).

All current isolates are either purple sulfur bacteria (class Gammaproteobacteria), non-sulfur bacteria (class Alphaproteobacteria), or green sulfur bacteria. The most well-studied purple bacteria isolates are *Rhodospseudomonas palustris* TIE-1 and *Rhodobacter ferrooxidans* SW2, which are both isolated from iron-rich ditches. Marine photoferrotrophs from the purple bacteria have also been isolated. All green sulfur bacteria isolates belong to the genus *Chlorobium*. The most well-studied of these is *Chlorobium ferrooxidans* strain KoFox (Heising et al. 1999), which exists only in co-culture with a heterotrophic bacterium and is from freshwater. The only marine photoferrotroph from the green sulfur bacteria which has been isolated is *Chlorobium* sp. strain N1, isolated from coastal marine sediments (Laufer et al. 2017).

Most studies with photoferrotrophs involve using aqueous Fe(II) as an iron source, but these organisms can also oxidize Fe(II)-bearing minerals such as magnetite (Byrne et al. 2015) or even use electrons from electrodes (Bose et al. 2014). During Fe(II) oxidation, Fe(III) oxyhydroxides form which are typically closely associated with the cells, forming cell-mineral aggregates (Schaedler et al. 2009). However, mineral formation inside the cells is not observed in organisms which are true photoferrotrophs, i.e., can be maintained indefinitely with just CO₂, Fe(II) and light and do not require any additional electron donors to be added. The mechanism by which photoferrotrophs avoid encrustation by minerals which form quickly when Fe(III) forms at circumneutral pH is still undefined but may be related to the formation of a low pH microenvironment observed around the cells (Hegler et al. 2010) or, more speculatively, the production of Fe(III)-complexing ligands (Croal et al. 2004; Kappler and Newman 2004). *Chlorobium phaeoferrooxidans* is the only isolated photoferrotroph which does not form cell-mineral aggregates (Crowe et al. 2017; Thompson et al. 2017).

Photon

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon, Meudon, France

Definition

A photon is an elementary particle that is the basic unit (quantum) of light and of all other forms of ▶ [electromagnetic radiation](#). The photon has no rest mass and no charge and by definition travels at the speed of light. It is characterized by very few parameters: its energy and its polarization state. Its energy E is directly related to the frequency ν of the electromagnetic wave it is associated with, through the relation $E = h\nu$, where h is the Planck constant.

As regards fundamental interactions, the photon is the quantum of the electromagnetic field. This means that it mediates the interaction between charged particles, that is, the electromagnetic force.

Photons belong to the broad family of bosons, which are described as the carriers of the various fundamental interactions and are a necessary consequence of physical laws having particular symmetries at every point in space-time. Because it is made of bosons, a collection of photons can present very specific properties, one of the best known being the laser or ▶ [maser](#) effect.

Photons exhibit wave-particle duality. In other words, they exhibit properties of both waves and particles. For example, a single photon follows the same path as the optical beam and can be refracted or reflected just as the electromagnetic waves which are solutions of Maxwell's equations, but it can also act as a particle, for instance, when extracting an electron from a metal (photoelectric effect).

Definition

The photosphere corresponds to the apparent visible surface of a star and especially of the Sun. It is a very thin shell where most of the light a star radiates is produced. Its thickness is less than one thousandth of the star's radius. Its temperature, which is typically between 3000 and 40,000 K, is one of the fundamental parameters characterizing a stellar type.

Definition

Photosynthesis is the metabolic process by means of which organisms capture light in order to carry out an ► [endergonic](#) synthesis of organic molecules. In a general sense, photosynthesis can be considered as the primary event in the process of converting the energy associated to photons into a gradient of electrochemical potential of protons across some biological membranes, that is to say, into a ► [protonmotive force](#).

Overview

Although initially photosynthesis was used to describe the events by means of which the energy of visible light was transduced in the synthesis of sugars from carbonic anhydride in plants and cyanobacteria, the phenomenon is more general, and in all the cases the primary events are not associated with such a synthesis, but with the translocation of protons across biological membranes as the thylakoid membrane of the chloroplast in plants or the cytoplasmic membrane in photosynthetic bacteria. The different photosynthetic mechanisms can be classified into three classes:

1. Direct coupling between absorption of photons and translocation of protons, the simplest mechanism of phototransduction. One example is bacteriorhodopsin, a family of monomeric membrane proteins with a prosthetic group (retinal) that suffers a conformational change as a consequence of the absorption of light. This causes a change in the pK of several residues of the protein amino acids, leading to the exclusion of protons and then to the origination of a protonmotive force. The reentry of protons through the ► [ATP synthase](#) yields ATP. In 1971, bacteriorhodopsin from halophilic archaea was shown to function as a light-driven ► [proton pump](#). In 2000, a new type of rhodopsins, proteorhodopsins, was found in marine bacteria. These proteins are present in most of the phototrophic microorganisms living in ocean surface waters.

2. Cyclic ► **electron transport**. This is the case of many purple bacteria as *Rhodobacter sphaeroides* (see Fig. 1a). A dimmer of bacteriochlorophyll whose maximum of absorption is at 870 nm (P_{870}) absorbs electromagnetic radiation and, in its excited state, has a very negative ► **redox potential**. As a consequence,

an electron from the dimmer can be transferred to another spatial closed molecule, as bacteriopheophytin. Eventually, the electron comes back to the dimmer of bacteriochlorophyll through a non-hemo Fe and a ubiquinone (UQ) molecule. In the transport of electrons, a bc_1 complex, similar to complex III in the

a Anoxygenic photosynthesis

b Oxygenic photosynthesis

Photosynthesis, Fig. 1 Examples of anoxygenic and oxygenic photosynthetic electron transport chains. **(a)** In purple bacteria (*left*) and green sulfur bacteria and heliobacteria (*right*), only one photosystem is operative. After excitation by photons, the bacteriochlorophyll of the reaction center (P_{870} or P_{840}) releases an electron to a cyclic (*left*) or a linear (*right*) transport chain. In the second case, an external electron donor (usually H_2S) reestablishes the fundamental state in P_{840} . **(b)** In cyanobacteria and plastids, two photosystems act in series allowing the

transport of electrons from water to $NADP^+$. The position of the different components is approximate to their reduction potential. *Arrows* indicate electron transfer and *broken arrows*, excitation by photons; *boxes* indicate the bacteriochlorophyll (or the chlorophyll) of the reaction centers; *gray boxes* indicate a multimeric electron transport complex; *circles* indicate small electron carriers; *gray circles* indicate the quinone pool. *PS I* photosystem I, *PS II* photosystem II, *cyt* cytochrome, *Fd* ferredoxin, *PC* plastocyanin

respiratory chain, is also implicated. As a consequence of this cyclic electron transport, a net exclusion of protons from the cytoplasm of the bacteria takes place, and a protonmotive force is generated. In this kind of photosynthesis, no direct reducing power is produced. In order to get this, a reverse transport of electrons coupled with the reentry of protons is needed. Moreover, the reentry of protons drives the synthesis of ATP by means of an ATP synthase. A main conclusion of these facts is the universality of mechanisms of the transduction processes in bioenergetics and a closely related evolutionary history of these mechanisms.

3. Noncyclic electron transport. In these systems electrons flow from an initial donor to a final acceptor, eventually producing reduction power, usually NAD(P)H. In plants and cyanobacteria, the initial donor of electrons is a water molecule (see Fig. 1b). The water-splitting reaction (water photolysis) as a consequence of the absorption of electromagnetic radiation is one of the most intriguing mechanisms in the biosphere. The releasing of molecular oxygen as a consequence of water oxidation (i.e., ► [oxygenic photosynthesis](#)) has had a dramatic effect on the evolution of the chemical composition of the Earth atmosphere, from an early anoxic planet to the current oxygen-rich atmosphere. A molecule of chlorophyll (named as P_{680}) in the excited state reaches a very negative oxidoreduction potential, leading one electron to a molecule of pheophytin, resulting in a chlorophyll with a positive charge. The pair chl^+/chl has a very positive redox potential ($\sim +1200$ mV), being able to accept one electron from the water molecules. All these processes take place in the named Photosystem II, a purple bacteria-like photosynthetic center. On the other hand, other chlorophyll (P_{700}), integrated in the Photosystem I (green sulfur bacteria-like photosynthetic center), in its excited state as a consequence of absorption of light, releases one electron that through a successive transport across different molecules, including ferredoxin, eventually reduces a molecule of $NADP^+$. The P_{700}^+ so produced captures the

electron originated in the Photosystem II, which is transported sequentially through plastoquinones, *bf* complex (very similar in molecular organization to complex III in mitochondria), and plastocyanin. The main contribution to the protonmotive force is originated in the *bf* complex. Thus, in these organisms, two different photosystems are working in series.

While in cyanobacteria the photosynthetic systems are localized in the cytoplasmic membrane, in plants all the processes take place in the chloroplast, in a highly organized internal membrane named thylakoid. As a consequence of the photosynthetic processes, protons are released to the interior of the thylakoid generating the protonmotive force, and by means of an ATP synthase, the transit of the internal protons to the stroma (space between the external membrane of the chloroplast and the thylakoid) yields ATP. Both the ATP so produced and the NADPH resulting from the noncyclic transport of electrons are necessary for the fixation of the carbonic dioxide and its conversion in different metabolites. These processes classically, and incorrectly, have been known as *light-independent reactions*.

Other microorganisms, as green sulfur bacteria and heliobacteria, also show a noncyclic electron transfer in their photosystems (Fig. 1a). However, there are two main differences with respect to the photosynthetic chains of cyanobacteria (and chloroplasts): they possess only one photosystem, and the initial electron donor usually is hydrogen sulfide instead of water. Oxygen is not a by-product of these photosynthetic chains, hence the name of anoxygenic photosynthesis. The organization of the photosystems of green sulfur bacteria is closely related to Photosystem I of cyanobacteria and chloroplasts. In the same way, Photosystem II is related to photosystems of purple bacteria.

Although the mechanism described above takes place in the reaction centers, the excitation of these centers does not occur by a direct absorption of light by such centers, but by the transfer of the excitation from other molecules grouped in complexes known as antennae, and is composed

of many molecules of chlorophylls and carotenoids. Except haloarchaea, all the other photosynthetic systems have antennae. The existence of these complexes of antennae has several advantages. On one hand, the turnover time of the photosynthetic center is about 100 s^{-1} , whereas the capacity of absorption of light for this center, even under very bright sunlight, is only one ► **photon** every second. This means that without other source of excitation, the photosynthetic center will be for most of the time not working. Antennae supplies continuously excitation to the reaction center, and so the kinetic impediment mentioned above is overcome. On the other hand, the molecule components of the reaction center only absorb radiation of certain ► **wavelength**, usually near the red. That means that photons with less wavelength would be discarded. The existence of the antennae avoids this problem, harvesting photons of lower wavelength and transferring the excitation to the reaction center by means of several mechanisms, mainly by resonance and by excitons. The structural organization of the antennae around the reaction center is very precise in order to get the optimization of the excitation transfer processes.

Regarding the origin and evolution of photosynthetic electron transport chains, several models have been proposed. Since oxygenic photosynthesis is the main source of molecular oxygen known, the study of the changes in atmospheric composition throughout the geological time is a key evidence to date the origin of Photosystem II, most probably by molecular evolution from an ancestral form similar to purple bacteria photosystems. In any case, the origin of the water-oxidizing ability remains obscure. Some authors propose that the two photosystem chains arose by fusion of gene repertoires from anoxygenic photosynthetic bacteria and the late emergence of a water-splitting enzyme. On the other hand, others postulate the existence of an ancestral cyanobacteria-like microorganism encoding both photosystem types and with the ability of expressing them differentially. This model postulates the loss of the switching ability or one or the other photosystem to explain the

origin of the oxygenic or the anoxygenic photosynthesis, respectively.

Basic Methodology

Spectroscopic techniques, mainly absorption and fluorescence spectra, have been one of the main methodologies in the study of photosynthetic mechanisms. For example, a loss of absorbance (bleaching) at a certain wavelength indicates the loss of an electron of a molecule absorbing at this wavelength. On the other hand, fluorescence has been a very useful technique for evaluating the order of the transmission of the excitation as well as the kinetic details of the processes.

Details about the chain of reaction involved in the transfer of electrons have been obtained by using similar techniques as those used for the respiratory chains, for example, using some specific inhibitors of the electron transport complexes.

The structural determination of photosynthetic systems, mainly through X-ray diffraction, has been decisive in order to know precisely the mechanism of the different events that take place in the photosystems. Unfortunately, many of them have a very large size, and the preparation of crystals is difficult. At present, only a few reaction centers and antennae of some bacteria are known at atomic resolution.

Key Research Findings

- The influence of light in the consume of CO_2 and in the liberation of O_2 by the plant was first described by Jean Senebier in 1796.
- In the middle of the twentieth century, Cornelius Bernardus van Niel demonstrated that photosynthesis is a light-dependent redox reaction. In this reaction an oxidable compound (not necessarily water) reduces CO_2 to yield sugars.
- The existence of two photosynthetic systems working in parallel was derived from the so-called *red drop* or Emerson effect. This author studied the evolution of O_2 by algae

illuminated at different wavelengths. In the range from 400 to 680 nm, O₂ evolved very effectively, but at higher wavelength, the production of O₂ decreased sharply, but this production was reestablished if the system was illuminating with a non-saturating light at 650 nm.

- Determination of the structure of the reaction center of photosystems, as well as of the antennae, by X-ray diffraction. The seminal works were developed on purple bacteria photosystems by several authors (Johann Deisenhofer, Robert Huber, and Hartmut Michel).

Applications

- Artificial photosynthesis
- Agriculture and the new challenges for photosynthesis research

Future Directions

- Structural determination at atomic resolution of reaction centers and antennae systems of cyanobacteria and plants. Although some details of this are known, further studies are necessary in order to understand completely the mechanisms of actuation.
- Artificial photosynthesis. This tries to merge some aspects of photosynthesis, as the conversion of sunlight, water, and CO₂ into sugars and O₂, or to produce a protonmotive force, by using artificial membranes.

Definition

Photosynthetic pigments are the molecules responsible for absorbing electromagnetic

radiation, for transferring the energy of the absorbed photons to the reaction center, and for photochemical conversion in the photosynthetic systems of organisms capable of photosynthesis.

Overview

Photosynthetic pigments derive their name from the fact they can absorb visible light (from Lat. pi (n)g(ere) – to paint + ment(um)). The molecules of photosynthetic pigments are quite ubiquitous and are always composed of chlorophylls and carotenoids. Chlorophylls consist of a porphyrin ring, which is bounded to an ion Mg^{2+} , attached to a phytol chain. Chlorophylls form part of reaction centers – where the photochemical conversion takes place – and antennas, or light-harvesting complexes, i.e., collectors of electromagnetic radiation, whereas carotenoids are found only in the antennas. Both types of molecules are found in “quasi-crystalline” structures in photosynthetic systems, associated with protein molecules that form part of biological membranes, either the cytoplasmic membranes of photosynthetic bacteria or thylakoid membranes inside plant chloroplasts. Chlorophylls found in bacteria are called bacteriochlorophylls. Photosynthetic systems also contain another pigment, pheophytin (bacteriopheophytin in bacteria), which plays a crucial role in the transfer of electrons in photosynthetic systems. Moreover, other pigments can be found in particular photosynthetic systems, such as xanthophylls in plants.

The oxidation-reduction potential of reaction center chlorophylls in an excited state as a consequence of the absorption of a photon can become very negative, which promotes the transfer of electrons to neighboring molecules, usually pheophytins. This is the primary photochemical reaction that takes place in reaction centers.

There is one class of pigment that exists only in halobacteria, called bacteriorhodopsin. It is composed of a protein attached to a retinal prosthetic group, which is responsible for the absorption of light photons, leading to a conformational change

in the protein, which results in the expulsion of the protons from the cell.

Definition

Phototroph is an organism that can use visible light as a primary ► [energy](#) source for metabolism, a process known as ► [photosynthesis](#). Phototrophs contrast with ► [chemotrophs](#), which obtain energy from the oxidation of organic compounds. Most phototrophs are autotrophs, also known as photoautotrophs, making use of the

energy obtained from photosynthesis to assimilate carbon dioxide (CO₂). Photoheterotrophs produce ATP using solar energy, but their source of carbon for biosynthesis is reduced organic compounds. From an ecological point of view, it has been considered that life on Earth is dependent on photoautotrophy, although the recent discovery of submarine strict chemolithoautotrophs is challenging this concept. Phototrophic organisms contain pigments that allow the use of light as an energy source.

Phyllosilicates, Extraterrestrial

Daniela Tirsch
German Aerospace Center DLR, Institute of
Planetary Research, Berlin, Germany

Keywords

Hydrated minerals · Mars

Synonyms

[Clay minerals](#); [Micas](#); [Sheet silica](#)

Definition

Term for hydrated minerals that consist of parallel sheets of silicate SiO_4 tetrahedra.

Overview

Phyllosilicates are usually built as alteration products of olivine- or magnesium-rich ► [rocks](#), often associated with hydrothermal weathering. They can also result from the transformation of primary ► [minerals](#) (e.g., feldspar). Their formation is controlled by bedrock composition, climate factors (temperature, pH-value, accessibility of liquid ► [water](#)), topography, time, and kinetics of mineral reaction. During the weathering process, OH groups are incorporated into the crystal lattice, leading to the hydration of these minerals. Thus, their existence is an indicator for the long-term availability of liquid water at the time of mineralization. Depending on their tetrahedral structure, phyllosilicates are grouped in dual- and triple-layer phyllosilicates. The silicate sheets are interleaved with layers of other elements. A typical characteristic of clay minerals, which constitute a subgroup of phyllosilicates, is their ability to expand and shrink in response to the reversible adsorption of water molecules.

Extraterrestrial phyllosilicates do not differ from terrestrial ones except for the abundance of individual mineral types. Typical phyllosilicates found on ► [Mars](#) are, for example, ► [kaolinite](#) ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$), smectite (e.g., montmorillonite $((\text{Na}, \text{Ca})_{0.33}(\text{Al}, \text{Mg})_2(\text{Si}_4\text{O}_{10})(\text{OH})_2 \cdot n\text{H}_2\text{O})$), and chlorite (e.g., chamosite $((\text{Fe}^{2+}, \text{Mg}, \text{Fe}^{3+})_5\text{Al}(\text{Si}_3\text{Al})\text{O}_{10}(\text{OH}, \text{O})_8)$). The bulk of the Martian phyllosilicates were probably built in a nonacidic aqueous alteration regime in ► [Noachian](#) times, which has been proposed to be termed the phyllosian period (Bibring et al. 2006). The various formation hypotheses include sedimentation and aqueous alteration in fluvial channels and standing bodies of water (e.g., Story et al. 2010), impact-induced hydrothermalism (e.g., Schwenzer and Kring 2009; Marzo et al. 2010), subsurface alteration

by hydrothermal groundwater circulation (Ehlmann et al. 2011), and pedogenesis (e.g., Le Deit et al. 2012).

Evolutionary tree; Tree of life; Universal tree of life

Definition

Phylogenetic trees, often called evolutionary trees, are tree-like diagrams depicting the evolutionary relationships among organisms or other entities (such as gene sequences) that derive from a **common ancestor**. Phylogenetic trees are usually drawn as bifurcating diagrams, so that technically they can be defined as noncircular connected graphs. They are composed of nodes and branches (or edges). Both branches and nodes can be internal or external. An internal node corresponds to the last common ancestor of all branches and nodes arising

from it (therefore, internal nodes are also called ancestral nodes). External or terminal nodes, also called leaves, represent the entities from which the tree was inferred. Phylogenetic trees can be rooted or unrooted (Fig. 1). In general, rooting a tree requires the use of an outgroup organism or sequence, which allows constructing directed or polarized trees (i.e., trees in which the order of changes occurring in the species or sequences can be inferred).

Overview

Phylogenetic trees are inferred using different kinds of information, in particular morphological and molecular characters. The aim of these trees is to provide an accurate representation of the evolutionary relationship between organisms or sequences using the evolutionary information contained in the characters. This information can be treated using different methods (such as distance, maximum parsimony, and maximum likelihood ones) to estimate the degree of relatedness of the units (e.g., organisms or sequences) for which the phylogenetic tree is constructed. Once the tree is constructed, it can be represented in different ways, which include: (1) cladograms, which only represent the branching pattern without drawing branch lengths proportional to the divergence between organisms or sequences; (2) phylograms, which show branch lengths proportional to the divergence (number of changes in

P

Phylogenetic Tree, Fig. 1 Phylogenetic tree of bacterial species based on ribosomal RNA sequence comparison. (a) Unrooted tree showing different elements of the tree;

(b) the same tree but rooted using two sequences of archaeal species as outgroup

the characters used) between organisms or sequences; and (3) chronograms, which have branch lengths that are proportional to the time of divergence between organisms or sequences. In addition, all these representations can be rooted or unrooted. Rooted phylogenetic trees are directed or polarized trees containing a node that corresponds to the most recent ancestor of all the leaves of the tree. This node is usually identified by using an outgroup, namely, an organism or sequence (or a set of them) that is known not to be part of the group for which the phylogenetic tree is constructed (i.e., the ingroup) but that have characters that are homologous to those used for the tree construction. Rooting the tree allows inferring the order of emergence of the different branches in the tree, as well as the order of evolutionary change in the states of the characters used to construct the tree. In contrast, unrooted trees do not specify the ancestry but just provide information about the relatedness among the branches.

The universal tree of life, also known as “the tree of life,” depicts the phylogenetic relationships among all living beings. It can be reconstructed using markers that are present in all species. The most famous version of the tree of life is based on the analysis of small subunit ribosomal RNA sequences which led to the classification of living beings into the three domains of life: Bacteria, Archaea, and Eucarya.

Definition

Phylogeny concerns the study of the evolutionary relationships among organisms or among ► [sequences](#) of biological macromolecules (DNA, RNA, or proteins) using information from morphological, structural, developmental, or molecular markers (the latter commonly called molecular phylogeny). Phylogeny implies that the organisms or sequences analyzed derive from a ► [common ancestor](#) (i.e., the common descent principle) and that evolution proceeds through a branching process. This means that species evolve and separate into different branches or disappear (extinction). The representation of this process can be done using ► [phylogenetic trees](#). Phylogeny has become the basis of modern ► [taxonomy](#),

commonly called “phylogenetic systematics,” so that the different taxa should represent monophyletic groups inferred by phylogenetic analysis.

Overview

Phylogenetic analysis is based on the comparison of characters found in the different entities (e.g., species or gene sequences) for which a phylogenetic tree is constructed. An essential requisite for a proper phylogenetic reconstruction is that those characters have to be homologous (namely, to have been inherited from a common ancestor) and they have to be variable. This means that they can exist in different forms, which are called character states (e.g., the four nucleotides A, T, C, and G for a site in a DNA sequence or the different morphologies of organisms). The information (called “phylogenetic signal”) that is analyzed by the phylogenetic approach is contained in the particular configuration of states of the characters examined. These characters are compared among the different organisms or sequences in order to estimate their degree of relatedness, which can be measured in different ways (see the section “[Basic Methodology](#)” below).

Basic Methodology

The simplest method of phylogenetic inference is the [phenetic](#) approach based on the construction of distance matrices based on overall similarity between the entities studied compared two by two (the simplest distance is the p-distance or the number of characters with different character states divided by the total number of characters, and it can be expressed as a percentage of similarity). More sophisticated methods include maximum parsimony, maximum likelihood, and Bayesian inference. These are called discrete data methods because they examine each character separately and look for the phylogenetic tree that best accommodates the corresponding information. Maximum parsimony, a method inspired by the cladistic approach, is intended to find the phylogenetic tree that minimizes the number of

changes required to explain the distribution of character states found in the set of organisms or sequences studied. Maximum likelihood and Bayesian inference require a model of character evolution (or substitution model), that is, a series of rules about the probabilities of change from a given character state to the other possible states. Using this kind of models, maximum likelihood estimates the probability for each character of the distribution of character states found in the set of organisms or sequences studied and tries to find the phylogenetic tree with maximum global probability for the entire set of characters analyzed. Bayesian inference has a similar basis, but it also evaluates the probability of the character data set for a given phylogenetic tree.

Distance methods are much faster than discrete data methods but they are much less informative: Their outcome is only a phylogenetic tree whereas the other methods also provide information about the evolution of the different characters along the tree. The only way to assure that the best phylogenetic tree has been found using the discrete data methods is to test all the possible trees to choose the most parsimonious or the most likely one. However, this is possible in practice only for data sets containing a very small amount of species or sequences. In fact, for a data set of size 10, there are 2,027,025 possible different bifurcating trees, and the number is of $\sim 2 \times 10^{20}$ different trees for 20 species. The latter are impossible to treat in a reasonable time using the complex parsimony or likelihood calculations. Therefore, different techniques of non-exhaustive exploration, called heuristic search methods, have been developed to search the tree space of all possible trees. Nevertheless, they do not assure retrieving the best tree.

Phylogenetic analysis can be biased by a series of data and methodological problems that have been characterized in the last decades. Stochastic errors arise when all character states have not changed following the same evolutionary pattern. This problem is particularly critical when a small number of characters are used for phylogenetic analysis. Therefore, there is a tendency to utilize as much characters as possible (the “total evidence” approach), though this can induce other

types of problems (the systematic biases) which can be exacerbated by the addition of increasing number of characters, especially when they are analyzed using models that do not describe correctly the evolutionary process. Convergent evolution is a well-known source of error that can lead to the inference of incorrect phylogenies. For example, parasitic species often have simple morphologies because they lose organs that are unnecessary since many functions are provided by their hosts. Therefore, parasites of different evolutionary origins may be artificially grouped together in phylogenies because of their convergent similarity. Molecular phylogeny can also be affected by convergence problems. For example, hyperthermophilic prokaryotes tend to have ribosomal RNA (rRNA) sequences rich in G and C nucleobases because they are more stable at high temperatures. Phylogenetic trees reconstructed using rRNA sequences analyzed with inadequate models can group hyperthermophiles of different origins just because their sequences may appear to be similar due to their high GC content. This type of compositional bias is a clear example of systematic error in molecular phylogeny because the artefactual result becomes stronger as more and more sequence data are used. This is also the case with fast-evolving species or sequences, which are affected by the so-called long-branch attraction artifact: the tendency to group fast-evolving entities irrespective of their true evolutionary relationships.

Key Research Findings

The findings of the application of phylogenetic analysis to the study of biological evolution and diversity have been numerous and very important, beginning with the recognition during the eighteenth and nineteenth centuries that many animal and plant fossils could be affiliated to groups still existing, or the discovery that contemporary birds are the descendants of an ancient dinosaur ancestor. However, it is thanks to the development of molecular phylogeny based on the analysis of DNA and protein sequences that the most radical

changes in our view of biological evolution have been possible. In particular, the first phylogenies based on the comparison of the rRNA gene sequences led to the discovery in the late 1970s that all living beings can be classified into three major groups or domains, Eukaryotes, Bacteria, and Archaea, the latter being unknown to the scientific community until then (Woese and Fox 1977). Molecular phylogeny has also demonstrated the endosymbiotic origin of mitochondria and chloroplasts from bacterial ancestors (alphaproteobacteria and cyanobacteria, respectively), as well as the importance of horizontal or ► [lateral gene transfer](#) in microbial evolution.

Applications

The applications of phylogenetic analysis are extremely diverse, from very basic to applied ones. It is the tool of choice to address a variety of evolutionary questions, not only the inference of the evolutionary relationships between species but also the evolution of genes (including gene duplications, horizontal gene transfer, etc.) and biogeography. Phylogeny has also a large spectrum of medical applications, including epidemiology studies and forensic medicine.

Future Directions

Phylogeny is a very active field of research in evolutionary biology. Particular effort is now devoted to take advantage of the huge amount of molecular data that are made available by the sequencing of complete genomes or large scale metagenome projects. This has launched a new field called phylogenomics, which is promoting active investigation to improve algorithms and models to cope with very big data sets.

Synonyms

[Environmental sequence](#); [Operational taxonomic unit](#); OTU

Definition

In microbiology, a phylotype is an environmental DNA sequence or group of sequences sharing more than an arbitrarily chosen level of similarity of a particular gene marker. The most widely used phylogenetic marker is the small subunit ribosomal RNA gene. Two prokaryotic sequences are generally considered as belonging to the same phylotype when they are more than 97–98% identical (for eukaryotes, the values generally used are in the 98–99% nucleotide identity range). In prokaryotic microbiology, phylotypes, often referred to as Operational Taxonomic Units (OTUs), are a proxy for ► [species](#).

Phylum

David Moreira and Purificación López-García
Unité d'Ecologie, Systématique et Evolution
CNRS UMR8079, Université Paris-Sud 11, Paris, France

Synonyms

[Division](#)

Definition

Plural, phyla. A phylum is a high-order taxonomic category in the hierarchical biological classification system. Situated below the domain and kingdom levels, it is above the taxonomic level of class. The term Division is used as synonym, particularly in botany. In prokaryotic microbiology, although the term phylum is preferred for taxa including cultivated members, the expression “Candidate Division” is used for clusters of environmental sequences that, phylogenetically, constitute groups equivalent to phyla for described species.

History

The term was coined in 1876 to mean a “division of the plant or animal kingdom” by the French naturalist Georges Dagobert, Baron Cuvier (1769–1832), from the Greek phylon “race, stock,” related to phyle “tribe, clan,” and phylein “bring forth.”

Materialism · Metaphysics · Physical theory · Physicalism · Supervenience

Synonyms

[Materialism](#)

Definition

Physicalism is the metaphysical thesis that everything is physical. According to this thesis, everything in the world, including chemical, biological, mental, and social entities and processes, is constituted by or results from physical entities and processes. In analytic philosophy, one might say that physicalism is the claim that everything supervenes on, or is necessitated by, the physical.

Overview

Physicalism is sometimes taken as synonymous to ► [“materialism”](#). Historically though, the word had a different meaning as it used to be associated with a particular linguistic thesis of positivist philosophers of the Vienna Circle. It is now generally understood as a metaphysical claim about the nature of the world emphasizing a connection to physics and the physical sciences (and no longer

solely to matter, as was initially the case with “materialism”). According to physicalism then, everything that exists is physical.

As such, this claim blends three types of questions, each of which is controversial on its own: What does it mean to say that *everything* satisfies a given condition? What does it mean for something to say that it satisfies the condition of being *physical*? And, is it *true* that everything is physical?

One answer to the first question is to appeal to the notion of supervenience. Accordingly, “everything is physical” is taken to mean that “everything supervenes on the physical,” or, in other words with the language of modal logic, that “no two possible worlds can be identical in their physical properties yet differ in some of their other properties such as their chemical, biological, mental or social properties” (e.g., Davidson 1970; Lewis 1986; Stalnaker 1996).

One way to answer the second question is to link the notion of a physical property to that of a physical theory. Accordingly, a “property is physical” is taken to mean that this property belongs to (or supervenes on) the type of properties that physical theory tells us about (e.g., Smart 1978; Chalmers 1996; Stoljar 2001).

Different answers to both questions are possible as they remain much controversial (as exemplified by the debate about nonreductive physicalism and emergence).

As to the truth question of physicalism, much debate arises in philosophy of mind: in particular, the existence of qualia (i.e., the felt qualities of experience) that would be distinct from the physical is considered as one of the most serious challenges to physicalism (e.g., Chalmers 1996), whereas the argument of the causal closure of the world (i.e., intuitively the idea that every cause is a physical cause) is usually taken as establishing physicalism (e.g., Kim 1993).

Definition

The term plankton comes from the Greek meaning to drift or wander and was introduced in 1887 by Victor Hensen to refer to biological matter that drifts in bodies of water (Mills 1989). The term phytoplankton refers to the photosynthetic species of the plankton community. Phytoplankton are a genetically diverse set of organisms that include the prokaryotic cyanobacteria and many eukaryotic groups (Hackett et al. 2007; Simon et al. 2009).

Overview

Evolutionary History

Microfossil and molecular clock evidence indicates that prokaryotes originated in the Archean and eukaryotes in the Proterozoic (Betts et al. 2018). Determining when these groups first became photosynthetic, first became planktonic, and whether they originally inhabited fresh or marine environments is extremely challenging. Analyses of extant cyanobacterial genomes indicate that photosynthesis may have been acquired relatively late in the evolution of cyanobacteria, perhaps not long before the rise of oxygen ~2.3 billion years ago (Soo et al. 2017), and the

currently dominant oceanic picocyanobacteria, *Prochlorococcus* and *Synechococcus*, did not emerge until the Cryogenian, ~850 to 635 million years ago (Sánchez-Baracaldo 2015). While the photosynthetic eukaryotic lineages trace their origins to the Proterozoic, the dominant eukaryotic phytoplankton groups in the ocean today, namely, the diatoms, dinoflagellates, and coccolithophores, arose in the Mesozoic (Falkowski et al. 2004; Katz et al. 2004). Dinoflagellates and coccolithophores exhibit their highest levels of morphological diversity in the Mesozoic, while the diatoms reach their highest diversity in the later part of the Cenozoic.

Diversity

The global estimate of marine phytoplankton richness based on microscopy ranges from 3444 to 4375 species in marine waters to about 14,000 in freshwaters (Sournia et al. 1991). A majority of the described marine species are dinoflagellates and diatoms, with a smaller number of haptophytes and green algae (Sournia et al. 1991; Simon et al. 2009). Recent molecular analyses are providing new insight into the diversity of phytoplankton. A study based on the DNA sequence of the V9 region of the 18S ribosome estimates the diversity of marine eukaryotic plankton (both photosynthetic and non-photosynthetic members) at ~150,000 operational taxonomic units (OTUs) (de Vargas et al. 2015). The highest levels of diversity are associated with the smallest size fraction examined, cells with diameters between 0.8 and 5 μm . The picoplankton include photosynthetic, mixotrophic, and heterotrophic members such as parasites and symbiotic hosts. While some taxonomic groups of phytoplankton are strictly photoautotrophs (depending strictly on light for energy), many of the eukaryotic groups are mixotrophic (meaning they acquire energy through a combination of photosynthesis and heterotrophic nutrition) (Stoecker et al. 2017).

Phytoplankton Functional Groupings and Their Biogeography

Phytoplankton species are often grouped into a modest number of clusters based on their

ecological or biogeochemical role, termed phytoplankton functional types. The major marine phytoplankton groupings are described below. In some cases, there is overlap between evolutionary history (taxonomic group), cell size, and ecological and biogeochemical function. Biogeochemically, while all phytoplankton species use N and P, only some use Si (primarily the diatoms), and only a few can fix N_2 into reduced nitrogen (cyanobacteria). The stoichiometry of both the macro- and trace elements requirements (especially Fe) and ability to acquire resources vary across many of these groups. Differences in elemental requirements and ability to acquire resources are important determinants of the biogeography of phytoplankton functional groups.

Cell Size

Phytoplankton cell size influences competitive ability for resources, sinking rate, grazing susceptibility, and ecological and biogeochemical function (Finkel et al. 2010). Traditionally ecological and biogeochemical studies have divided the phytoplankton into three size classes (Sieburth et al. 1978): the picoplankton (0.2 to about 2–3 μm (10^{-6} m) in cell diameter), the nanoplankton (2–20 μm), and the microplankton (20–200 μm). Commonly, picophytoplankton communities are dominated by picocyanobacteria, while diatoms and dinoflagellates often constitute the largest fraction of the microplankton communities. Generally small cells thrive in stable and lower nutrient conditions, and larger cells predominate in environments with episodic and higher nutrient concentrations. Furthermore, larger phytoplankton are associated with higher trophic (fish yield) and carbon export efficiency (but see Richardson and Jackson (2007)).

Cyanobacteria

Cyanobacteria are often divided into two functional groupings: the (1) non-nitrogen-fixing picocyanobacteria and (2) nitrogen-fixing cyanobacteria. The dominant non-nitrogen-fixing picocyanobacteria in the ocean are dominated by two genera: *Prochlorococcus* and *Synechococcus* (see Partensky et al. 1999). Both are solitary coccoid species, but they differ in size and

pigment composition. *Prochlorococcus* is smaller than *Synechococcus*, 0.6 versus 0.9 μm in diameter, and uses divinyl chlorophyll a/b versus phycobilisomes. These differences in cell size and pigment composition influence their competitive ability under different nutrient and light regimes. *Prochlorococcus* often dominates phytoplankton biomass in much of the oligotrophic open ocean and can be found both in surface waters and deeper in the euphotic zone. *Synechococcus* is common in the surface of the oligotrophic ocean and increases in abundance and biomass in areas with episodic and higher nutrient inputs. *Prochlorococcus* has a more restricted geographic distribution and is found at a narrower range of salinities and warmer temperature than *Synechococcus*.

Nitrogen-fixing cyanobacteria convert N_2 into ammonia, providing a biologically useful source of fixed nitrogen to aquatic ecosystems that stimulates photosynthetic carbon fixation and export into the deep sea. Nitrogen fixation is catalyzed by the enzyme nitrogenase that is inactivated by oxygen. Many photosynthetic nitrogen-fixing organisms isolate nitrogenase in a specialized cell, termed a heterocyst, which isolates nitrogenase from oxygen. There are several single-celled, nitrogen-fixing cyanobacteria and non-heterocystous colonial species that segregate nitrogen fixation and oxygenic photosynthesis over time or across the cell or colony. Common open-ocean marine nitrogen-fixing cyanobacteria include the non-heterocystous colonial *Trichodesmium*, the single-celled *Crocosphaera watsonii*, and the photo-heterotrophic (does not use CO_2 as a C source) haptophyte symbiont UCYN-A (Martínez-Pérez et al. 2016). Common heterocystous forms include the free-living genera *Nodularia* and *Anabaena* and the diatom symbiont *Richelia intracellularis* (Sohm et al. 2011). *Nodularia* and *Anabaena* are typically found in cooler, more brackish, coastal regions, such as the Baltic Sea. In oligotrophic oceans, diatom diazotroph (can grow without external source of fixed N) associations (DDAs) provide biologically available nitrogen to diatom hosts (Villareal 1994). Common diatom hosts include *Hemiaulus* and

Rhizosolenia with the nitrogen-fixing symbiont *Richelia*. DDAs are especially well documented in the western tropical North Atlantic near the Amazon river plume but may be much more widely distributed (Subramaniam et al. 2008).

Picoeukaryotes

The photosynthetic picoeukaryotes are taxonomically diverse, many (but not all) species are flagellated (phytoflagellates), and many are mixotrophs. Many of the picoeukaryotes contain only a single mitochondrion, Golgi apparatus, and chloroplast. Photosynthetic picoeukaryotes can reach densities between 10^3 and 10^5 cells per milliliter in surface waters (see Massana 2011) and tend to reach their largest relative abundances in moderately oligotrophic to mesotrophic conditions. Traditionally the picoeukaryotes are difficult to identify by light microscope, but molecular methods provide new insight into their spatial and temporal controls. Prasinophyceae, Pelagophyceae, Bolidophyceae, and Pinguiphyceae are common groups of photosynthetic picoeukaryotes found in the ocean.

Calcifying Coccolithophores

Coccolithophores, most notably the nanoplankton *Emiliania huxleyi*, which forms large blooms, produce inorganic carbon as well as organic carbon. Coccolithophores are covered in calcite scales (termed liths), which may affect predation rates and light harvesting. Their production (Monteiro et al. 2016) has a direct effect on alkalinity, dissolved inorganic carbon, and pH. Some species of coccolithophores are particularly sensitive to changes in pH and may be strongly affected by ocean acidification (Riebesell et al. 1993). The downward flux of liths made of CaCO_3 removes carbon from the surface ocean and augments the biological pump of organic carbon.

Silicifying Phytoplankton

Diatoms are a dominant group of phytoplankton, responsible for almost half of all marine primary production. They range in size from 2 to several 1000s of micrometers in diameter (Finkel et al. 2005). Despite this diversity, they are best known for their species, which grow rapidly, are strong

competitors for nutrients, and form large, intense blooms. Diatoms play an important role in supporting fish production and in the export of carbon into the deep sea (Tréguer et al. 2017). Notably, diatoms have an obligate requirement for silicon to form a rigid frustule as part of their cell wall. Small differences in frustule structure are diagnostic of individual species. Although diatoms are the ecologically dominant silicifying phytoplankton group, several other phytoplankton groups incorporate Si, for example, silicoflagellates construct a skeleton of fused Si bars and rods. Some of the cyanobacteria have been shown to have a requirement for a trace amount of Si.

Dinoflagellates

Dinoflagellates are a diverse group with intermediate- to large-sized species and incorporate autotrophs, heterotrophs, and a large number of mixotrophs. Morphologically, they are characterized by two flagella and, for many species, the presence of an armored cell wall composed of chemically resistant organic plates called theca. Dinoflagellates generally have slower growth rates than diatoms (Tang 1996) and tend to be found in higher abundance in warmer, stratified waters.

Biogeochemical and Ecological Significance of the Phytoplankton

Phytoplankton perform approximately half of the photosynthesis on Earth: 45–50 Pg C per year (Falkowski et al. 1998). Photosynthesis splits water molecules, releasing O₂ into the atmosphere, and converts inorganic dissolved carbon and nutrients into biomass. As a consequence, phytoplankton influence the biogeochemistry of the Earth and fuel aquatic and marine food webs. Although total phytoplankton productivity is approximately the same as land plants, the total biomass of phytoplankton is a tiny fraction of land plant biomass, so carbon flows from inorganic forms through phytoplankton and into other pools relatively quickly. Most of the organic carbon fixed and oxygen evolved by phytoplankton is quickly respired by grazers or the microbial decomposers, reversing the process of

photosynthesis. A small fraction of the organic carbon is transferred to long-lived organisms such as fish and marine mammals. Another small fraction is exported from the pelagic (surface sunlit) zone into the deep ocean and sediments. Carbon exported to the deep ocean and sediments is effectively removed from interactions with the atmosphere for thousands to many millions of years, respectively. It is this long-term export of carbon into the deep ocean and sediment that regulates atmospheric CO₂ and O₂ content.

Phytoplankton community composition and primary production vary in space and time (Finkel 2014). Generally, biomass and production are highest in regions where light and nutrients in the upper mixed layer of the ocean are sufficient to support high rates of photosynthesis, for example, in coastal and upwelling systems. In contrast, biomass and primary production becomes diminished and less variable in regions with deep surface mixed layers where average light experienced by phytoplankton is low, as occurs over much of the high-latitude oceans in winter and in low-nutrient regions, such as the subtropical central oceanic gyres. Inorganic nitrogen and iron and, to a lesser extent, phosphate are the most common elements limiting marine phytoplankton production. Other factors that influence the primary production include inorganic carbon concentration and pH, light dose, period, quality, turbulent mixing, and species interactions, as well as loss due to grazing by zooplankton and infection by parasites and viruses. The taxonomic and size structure of phytoplankton communities is shaped by environmental conditions and biotic interactions and, in turn, influences the structure of the food web and fraction of primary production that is ultimately exported out of the ocean surface to the sediments.

Basic Methodology

Traditionally phytoplankton have been collected via nets and water samples and identified using light microscopy (Mills 1989). Molecular analyses are increasingly being used to characterize phytoplankton community diversity (de Vargas

et al. 2015). Chlorophyll-*a* is often used to estimate phytoplankton biomass in the field, and satellite remote-sensed chlorophyll is used to generate global estimates of both biomass and net primary production (Falkowski et al. 1998).

- Nitrogen Fixation
- Photosynthesis

Key Research Findings

Warming ocean temperatures over the coming century will lead to wide-ranging changes in the physical, chemical, and biological state of the ocean. The amount of phytoplankton biomass, their rate of production, and the species present will be modified as much of the surface ocean becomes warmer and lower in nutrients. There is evidence that increasing warming and water-column stratification will reduce phytoplankton primary production (Behrenfeld et al. 2006) and that increasing CO₂ concentrations could fundamentally alter rates of nitrogen fixation by key cyanobacteria such as *Trichodesmium* (Hutchins et al. 2007) and calcification by coccolithophores (Riebesell et al. 1993). Taken all together, these effects are expected to lead to widespread changes in phytoplankton community structure and the global biogeochemical cycles of carbon and nitrogen.

Future Directions

Wider application of molecular tools, culture work, and statistical analyses will further improve our understanding of phytoplankton and how these species respond to different chemical and physical stimuli. A better knowledge of how environmental conditions influence functional types will enable improved models of production, export of carbon to the deep ocean, and changes in trophic transfer efficiency through the food web.

Definition

A piezophile (adjective – piezophilic) is an organism that lives under elevated hydrostatic pressure. While piezotolerant organisms only tolerate high pressures, piezophiles grow better under high pressures, and strict or obligate piezophiles require pressures above atmospheric pressure for growth. Piezophiles are known among vertebrates and invertebrates but prokaryotic piezophiles (Bacteria and ► [Archaea](#)) are the most extensively studied. They live in various habitats that are exposed to elevated hydrostatic pressure (deep aquifers, deep oil reservoirs, etc.), but the best known are from the deep ocean floor.

Overview

Hydrostatic pressure is a function of the weight of liquid above a given surface. Hydrostatic pressure is expressed in different units: $1 \text{ kg cm}^{-2} = 1 \text{ atm} = 1 \text{ bar} = 0.103 \text{ MegaPascal (MPa)}$. Hydrostatic pressure increases 0.103 MPa every 10 m of water. At the seafloor in the Marianna Trench (10,790 m), hydrostatic pressure is about 110 MPa. Study of piezophilic organisms requires the use of bioreactors that simulate high pressure conditions. After many years of research on this topic, microbiologist A. Yayanos (Scripps Institution of Oceanography, San Diego, USA) concluded that piezophily is a common property for bacteria isolated from cold deep oceans at depths from 1957 to 10,476 m. He observed that in cold oceans, there is a piezophily threshold at about 1800–2000 m, and that piezophily increases with the depth of capture. A. Yayanos was the first to isolate, from a dead amphipod collected at the Marianna Trench, the first strict piezophile, strain MT 41, that grows optimally at 2 °C and 69 MPa, with a generation time of 25 h. This organism was unable to grow at pressures below 39 MPa, and died when exposed at

atmospheric pressures. Only known for ► [psychrophiles](#) for many years, piezophilic organisms have recently been discovered for hyperthermophilic Archaea living at deep-sea hydrothermal vents. D. Prieur's laboratory (University of Brest, France) isolated the archaeon *Pyrococcus yayanosii* strain CH1 from samples collected at 4100 m from the mid-Atlantic Ridge. This strictly anaerobic organism grows optimally at 95 °C and 52 MPa, with a generation time of 51 min, and requires more than 15 MPa for growth. For bacteria, the cellular membrane and cell wall are involved in mechanisms of adaptation to elevated hydrostatic pressure. When grown at increasing pressures, piezophiles showed an increase in long chain polyunsaturated fatty acids located in the cell membrane. Also, it was found that specific porins located in the outer membrane of Gram-negative organisms were expressed with increasing pressures. Further studies on piezophiles will require the development of innovative techniques, such as diamond anvil cells, that allow microorganisms living under pressure to be imaged and Raman spectroscopy among other techniques to analyze their metabolism.

Definition

The Archean Pilbara Craton in northwestern Australia is a nearly circular piece of generally low-grade granite-greenstone crust, whose boundaries are defined by aeromagnetic and gravity anomalies and by flanking Proterozoic orogenic belts. The northern part of the craton is well exposed over an area of 530×230 km and is divided into several discrete terranes with distinct geological histories from 3.52 to 3.11 Ga that were stitched together by granites and overlain by late sedimentary basins during accretion and subsequent crustal relaxation from 3.07 to 2.83 Ga. The Pilbara Craton is famous for containing some of the Earth's oldest well-preserved rocks and fossil ► [stromatolites](#) and is a location for several astrobiology analogue sites and ► [Archean drilling projects](#) (see single entries listed below for a detailed description of those Pilbara's localities of astrobiology interest).

Overview

The Archean Pilbara Craton consists of five terranes, five late-tectonic, dominantly clastic sedimentary basins, a variety of granite suites, and a suite of large layered mafic-ultramafic igneous complexes (Fig. 1: Van Kranendonk et al. 2007). Terranes include the 3.53–3.17 Ga East Pilbara Terrane, representing the ancient nucleus of the craton; the ≥ 3.18 Ga Kurrana and ≥ 3.27 Ga Karratha terranes, which have older Nd-model ages and may represent rifted fragments of the ancient nucleus; c. 3.20 Ga Regal Terrane of ► [komatiites](#) and basaltic rocks; and juvenile volcanic rocks of the c. 3.12 Ga Sholl Terrane, interpreted as a rifted oceanic arc complex (Smithies et al. 2005).

The East Pilbara Terrane is underlain by the 3.53–3.17 Ga Pilbara Supergroup, which consists of four thick, autochthonous volcano-sedimentary

Pilbara Craton, Fig. 1 Simplified geological map of the northern Pilbara Craton, showing the East Pilbara Terrane, West Pilbara Superterrane, Kurrana Terrane, and the distribution of the c. 3.02–2.93 Ga De Grey Supergroup in the

Mallina Belt (MB), Mosquito Creek Belt (MCB), and areas in between. Colored or gray dots denote whole-rock Nd model ages

groups deposited on granitic crust up to 3.82 Ga old (Fig. 2). The lower three groups were erupted episodically to 3.24 Ga from melts derived from both fertile mantle and progressively depleted subcontinental mantle, leading to a thick mantle root. The stratigraphically highest Soanesville Group was deposited during rifting of East Pilbara Terrane margins at c. 3.18 Ga, followed by ocean closure at 3.12 Ga and terrane accretion at 3.07 Ga. Diverse evidence for life is preserved at a variety of levels throughout the supergroup and elsewhere through the craton (Van Kranendonk et al. 2007).

The dominantly coarse clastic De Grey Supergroup was deposited across the whole of the craton during post-orogenic collapse (3.01–2.99 Ga) and subsequent regional orogeny (2.97–2.91 Ga). Major depositional basins include the c. 3.02 Ga Gorge Creek Basin across the whole of the craton, and the 2.97–2.94 Ga Mallina and Mosquito Creek basins (Fig. 1). Lithospheric extension occurred at c. 3.02 Ga and 2.97–2.95 Ga, followed by compressional deformation at 2.94–2.905 Ga during accretion of Kurrana Terrane (Van Kranendonk et al. 2007).

process of conjugation involves a donor cell, which contains a particular type of ► [plasmid](#), a conjugative plasmid, and a receptor cell. Several plasmid genes are involved in the synthesis of sex pili. Only donor cells produce pili. Pili allow specific pairing between the donor cell and the recipient cell. The pili make specific contact with a receptor of the recipient cell and then retract, pulling the two cells together. When the contact between the donor and the recipient cells becomes stable, the plasmidic DNA is then transferred from one cell to the other. Through this mechanism, advantageous genetic traits can be disseminated among a population of bacteria. Not all bacteria have the ability to create sex pili; however, sex pili can interchange genetic information between bacteria of different species.

Pili

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Pili are short filamentous structures composed of protein that extend from the surface of the cell. Pili are similar to fimbriae, but in general are longer and only one or a few pili are present on the cell surface. A pilus is typically 6–7 nm in diameter and is primarily composed of oligomeric pilin proteins. Although possibly involved in cell attachment, as are fimbriae, pili are clearly involved in the process of ► [conjugation](#). The

Definition

Pillars are elongated structures made of molecular gas and interstellar dust.

Observed at the interface between HII regions, created by massive stars, and the associated molecular cloud, pillars are shaped by the stellar feedback of massive stars. This is mostly due to strong UV radiation but stellar winds can also play a role. Pillars are composed of a head facing the UV radiation, a tail elongated by ionization pressure, and a base where the initial clumpy structure within the parent molecular cloud was hit and transformed. They are still attached to the molecular cloud, while free-floating objects are commonly called globules.

History

The use of the word “pillars” in astronomy to describe an astronomical feature probably started in 1995. No clear occurrence in scientific paper abstracts (via ADS search) is retrieved before 1996, except for “pillars of cosmology,” with the meaning of foundation, or “sun pillar” in a rainbow. *Pillars of Creation* were first mentioned as the title of an image release aiming at publicizing observations of the Hubble space telescope in November 1995. The image exhibits three columns of interstellar matter and the text introduced them as “Undersea corral,” “Enchanted castles,” “Space serpents,” and then “incubators of new stars.” The title of the press release, including images and texts, clearly referred to the scientific paper: *Embryonic stars emerge from interstellar “Eggs.”* Seven months later, the scientific publication by Hester et al. (1996) resumed the observations with the title: *Hubble Space Telescope WFPC2 Imaging of M16: Photoevaporation and Emerging Young Stellar Objects*. No mention of the pillars is present in the whole paper. Hester et al. preferred “elephant trunks” and focused the study on the evaporating gas globules (EGGs) at the tip of the trunks. Since, “pillars” or “elephant trunks” were put forward in various publications, from scientific papers to press releases on results from infrared space telescopes like Herschel,

Spitzer, or WISE. The suggestive comparison of these elongated ionized gas objects and massive megaliths was studied by Kessler (2006). It was proposed that the Hubble images were produced with a romantic landscape iconography inspired from American painters in late nineteenth century like Thomas Moran and his *Chasm of Colorado*. The *Pillars of Creation* image symbolizes the ambivalent attitude and difficult choice to adopt between disseminating a valuable scientific result and making a pretty picture, the balance between scientific research and art powerful suggestiveness.

Overview

In star-forming regions within molecular clouds, stellar feedback in the form of ionizing radiation and stellar winds forms elongated, protruding gas structures at the interface between the ionized gas (HII region) and molecular clouds. Early examples of such structures can be found in Minkowski (1949) and Frieman (1954). Since, they were named as “comet-tail,” “elephant trunk,” “speck,” “teardrop,” and somehow connected to cometary globules. These globules are bubbles of cold gas that are inside the HII region and disconnected from the molecular cloud. Elephant trunks are cometary globules with tails that are attached to the molecular cloud. With the Hubble Space Telescope image of the Eagle Nebula released in 1995, but published in 1996 (M16, Hester et al. 1996), the term “pillar” was introduced to describe the features of a precise structure: a column-like shape and a physical connection to the gas reservoir of the molecular cloud. Note that the term pillar was not used in the scientific paper but imposed by the title of an image release. Typical characteristics of pillars include: a long (typical aspect ratio of at least a few) head-tail structure pointing toward the illuminating source; a bright rim at the edge of the head; a concentration of mass at the head, which might form stars; and a complex velocity structure that can be due to rotation with a period of 1–7 Myr, helical motion, and an intrinsic velocity gradient (e.g., Gahm et al. 2006).

Pillars are typically 1–4 pc long and 0.1–0.7 pc wide (Schneider et al. 2016; Sofue 2020). Star formation might be observed in the dense head of the pillars (e.g., Sugitani et al. 1989) and can lead to spectacular jets from proto-stars escaping of the head (e.g., HH901/902 in the Carina nebula, Smith et al. 2010). Despite these signatures, it is still unclear whether the star formation is indeed triggered by stellar feedback in these structures.

Basic Methodology

Infrared observations with the Herschel space observatory and the Spitzer space telescope revealed many more pillars in HII regions where OB stars have already formed, indicating that the UV radiation from massive stars plays a key role in their formation and possibly to stars inside. HII regions can have very complex shapes depending on the distribution of the ionizing sources and the initial structures in the surrounding gas. They range from spherical bubbles (e.g., RCW120, Zavagno et al. 2010), bipolar nebulae (e.g., RCW 36, Minier et al. 2013) to complex and large regions like Cygnus X OB2 and OB9 (Schneider et al. 2016). Dense layers of gas and dust are observed at the interface between the HII regions and their parent molecular clouds (e.g., Thompson et al. 2011; Zavagno et al. 2010). All around the inner shell of HII regions, elongated columns/pillars of gas are observed pointing toward the ionizing sources and usually connected to the molecular cloud (e.g., M16, Fig. 1). Various scenarios have investigated the physical connection between the formation of these clumpy structures and the appearance of pillars and globules. The collect and collapse scenario (see Elmegreen and Lada 1977) proposed that the shell could become sufficiently dense enough thanks to cooling of the swept-up gas, to reach the gravitational instability and therefore form dense condensations. Bertoldi (1989) proposed that cometary globules could be the result of the radiative implosion of an isolated gravitationally stable condensation. Mackey and Lim (2010) explained pillar formation by the shadowing effect of clumps in the density field. Parsec scale

simulations showed that most of clumps and pillars could be formed from the interaction between the turbulence of the molecular cloud and the ionization (e.g., Gritschneider et al. 2010). Tremblin et al. (2013) proposed that the most important parameter for the formation of pillars and clumps at the interface is the degree of curvature of the dense shell perturbed by preexisting structures. A high curvature triggers the collapse of the shell on itself to form pillars whereas low curvature only triggers the formation of dense clumps that are accelerated with and remain in the shell. The level of turbulence compared to the pressure of the HII region and the initial morphology of the molecular cloud would be key ingredients for the formation of clumps, pillars, and cometary globules.

Key Research Findings

With the infrared and submillimeter wave data provided by Herschel and Spitzer, complementing atomic and molecular line emission observations, understanding pillar formation was possible thanks to comparison between observations and numerical simulations. A prototypical example of pillars are the features observed in M16 (Fig. 1). Other pillars can be observed in the Rosette Nebula, Cygnus X, Carina, M8, NGC6357, NGC2264, NGC7822, and W5, for instance (Fig. 2, e.g., Schneider et al. 2012a, b; Deharveng et al. 2012). There are, however, regions of massive star formation that do not show prominent pillars (RCW120, for example). The Eagle Nebula (M16) is located in the constellation of Serpens at 1.8 kpc from the Sun. A young stellar cluster NGC 6611 is ionizing the molecular gas of this star-forming region (Fig. 1). The principal ionizing sources are O4 and O5 stars whose combined ionizing flux is of order $2 \times 10^{50} \text{ s}^{-1}$. The region is chemically rich and spectral line studies of the region are numerous (e.g., White et al. 1999; Schuller et al. 2006; and many others). Flagey et al. (2011) studied the dust spectral energy distribution (SED) using Spitzer data. They showed that the SED could not be accounted for by interstellar dust heating by UV radiation but

an additional source of heating was needed to match the mid IR flux. They proposed two possible origins: stellar winds or a supernova remnant.

Herschel provided new observations on the region, and Hill et al. (2012) studied in detail the impact of the ionizing source on the initial

temperature of prestellar cores located at the edge or deep into the molecular gas and did not find evidence for an extra source of heating. Recent SOFIA (Stratospheric Observatory for Infrared Astronomy) observations of the 158 micron line of ionized carbon in various galactic massive star forming regions (Schneider et al. 2020) revealed expanding bubbles seen in this line and emphasized the importance of stellar winds for the dynamics of the gas.

Tremblin et al. (2013) revisited the Herschel data and confronted them to numerical

simulations of pillar formation. Using a crest-detection algorithm on column density maps, pillars appear as coherent structures pointing toward the ionizing sources and connected at the base to the rest of the molecular cloud by a triple point in the interstellar filament skeleton (Fig. 3). A nascent pillar was detected at the south of the Pillars of Creation and another one in the Rosette Nebula whose velocity structure is consistent with numerical simulations (Fig. 3). The velocity field has a characteristic pattern predicted by numerical simulations, showing that the compressed shell of

The white crosses indicate the O stars

Pillars, Fig. 4 Pillar formation during the ionization of a turbulent molecular cloud. The top panels are two global column density snapshots of the simulation during the expansion of the ionized gas, the ionization is coming from the top of the box. The bottom panels are local density cuts with the velocity field represented by the black arrows. The left panel is a cut before the curved compressed layer (dense layer in yellow) collapses in on itself. The velocity field (black arrows) shows that the two sides of the curved layer are going to collide at the center. The right panel is a cut after the collapse, when the pillar is formed. After the collapse the pillar is connected to the rest of the compressed layer and moves down as shown by the velocity field. (Credit: P. Tremblin)

gas is curved and collapsing in on itself to form the elongated structure (Fig. 4). Another interesting feature that was discovered in pillars and globules is the fact that they show signatures of rotation (Gahm et al. 2006; Schneider et al. 2012b). The origin is not yet clear; it can be due to a residual momentum from the turbulent molecular cloud and/or the result of a magnetic field that is twisted around the pillar.

Summarizing the observations and numerical works propose a consistent picture of the formation of pillars and globules: (1) Pillars are formed when the shell is sufficiently curved to collapse in on itself. (2) If not sufficiently curved, formation of clumpy condensations is triggered inside the shell. (3) Pillars can detach from the parent molecular cloud when the turbulent ram pressure of the gas is bigger than the pressure of the ionized gas

and appear then as free-floating globules. This scenario is supported and extended with the proposition of an evolutionary sequence (Schneider et al. 2016) in which pillars evolve into globules, which in turn then evolve into other features such as evaporating gaseous globules (EGGs), transient condensations or proplyds (protoplanetary discs), or proplyd-like objects. Gravity-based scenarios such as the Rayleigh Taylor instability or more recently the remains of an accretion flow are ruled out by the velocity field structure in the case of the Pillars of Creation. All previous models do not predict a collapsing shell that is observed in the case of the nascent pillar in the Rosette Nebula. The structures both in M16 and Rosette are consistent with the interaction between ionization and turbulence, although other scenarios might still happen in other regions.

Applications

A direct consequence of this pillar formation scenario is that a preexisting dense clump will curve the shell around it, trigger the collapse and the formation of a pillar while a low-density perturbation will not sufficiently curve the shell to trigger the pillar formation. Instead, a dense clump is subsequently formed in the shell by the accumulation of matter triggered by the perturbation. This effect has been simulated in Tremblin et al. (2013) and also in Minier et al. (2013) in the special case of RCW36. Therefore, star formation happening at the tip of pillars is likely to happen even without ionization, while star formation in dense clumps in the shell is likely to be triggered by the feedback.

Future Directions

With the statistics of YSOs located at the edge of ionized bubbles (e.g., Thompson et al. 2011), it becomes clear that star formation triggered by the feedback of massive stars is indeed frequent and an important ingredient for the understanding of galactic star formation. Pillars, globules and clumpy condensations, and more generally HII region morphology are tools to disentangle physical phenomena responsible for star formation in a molecular cloud under the influence of high-mass star radiative feedback.

Pillow Lava

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble,
France

Definition

Pillow lava is a form of effusive (i.e., erupted at the surface) ► [igneous rock](#) which results when low-viscosity magma such as basalt erupts under water. Pillows are irregular tube-like structures, circular to elliptical in cross-section, typically 30 cm to about 1 m in diameter. They form when the crust of a lava flow, or of another pillow, fractures to allow the extrusion of a spurt of lava. A thin elastic crust forms at the surface so that lava continues to flow into the interior of the tube or pillow. Pillow lavas are common in all types of modern submarine volcanic settings – ► [midocean ridges](#), oceanic islands, and island arcs – and they form a common layer of the ► [oceanic crust](#) (Layer 2A) and are the most common volcanic feature in well-preserved Archean ► [greenstone belts](#). Pillow lava has received much attention by astrobiologists for the occurrence of tubular microscopic structures in samples of Archean age that could be related to biological activity (Furnes et al. [2004](#)).

Definition

These two NASA Pioneer probes were part of the Pioneer program to explore the Solar System. Pioneer 10 and 11 were aimed to visit the ► [Jupiter](#) and ► [Saturn](#), the two Giant planets of the outer Solar System. Pioneer 10 was launched from Cape Canaveral on March 2, 1972. It flew by Jupiter on December 3, 1973 and then continued its trip having gained sufficient momentum to

Pioneer Spacecraft,

Fig. 1 The drawing of the pioneer plate with explanations. (Photo NASA)

escape the Solar System. The last contact with the probe was on January 23, 2003, while it was heading toward the Aldebaran constellation that it will reach in about 2 million years. Pioneer 11 was launched as scheduled almost 13 months after its sister spacecraft on April 5, 1973. The spacecraft arrived at Jupiter and observed the planet's red spot on December 2, 1974 before heading toward Saturn. The spacecraft reached Saturn on September 1, 1979. The last contact with Pioneer 11 occurred on November 1, 1995.

The two identical spacecrafts were equipped with radioisotopic thermoelectric generators and have a dry mass of about 257 kg. Pioneer 10 carried a payload of 11 scientific instruments; Pioneer 11 carried one instrument more. The sister probes were designed to study the target ► **planets** and their satellites as well as the ► **space environment**, the solar wind, the cosmic rays, and the planetary and cosmic ► **magnetic fields**. Pioneer probes are recognized for their achievements (first photos from Jupiter, Saturn, Saturn's moons, ...). Both spacecrafts carry a gold-anodized plate (Fig. 1) designed by Carl Sagan, Linda Salzman-Sagan, and Frank Drake with a message to extraterrestrial

civilizations that they may encounter about the origin of the spacecrafts. They are also known for the detection of the so-called Pioneer anomaly. A Doppler drift in the radio signal demonstrated a slight unexpected change in the acceleration of the probes. The finding remains poorly explained to the present day and is of great interest to theoretical physics and cosmology. Nevertheless, some hypotheses have been published (Foot and Volkas 2001).

Synonyms

[Proton-induced X-ray emission](#)

Definition

Proton-induced X-ray emission (PIXE) is a technique used in the determination of the elemental makeup of a material or sample. Bombardment with MeV protons produced by an ion accelerator causes inner shell ionization of atoms, and outer shell electrons drop down to replace inner shell vacancies with certain allowed transitions. X-rays of a characteristic energy of the element are emitted and provide information about the composition of the sample. PIXE is a powerful yet nondestructive elemental analysis technique now used routinely. Recent extensions of PIXE using tightly focused beams (down to 1 μm) give the additional capability of microscopic analysis. This technique, called microPIXE, can be used to determine the distribution of trace elements with high spatial resolution in a wide range of samples.

Planet

Tilman Spohn
International Space Science Institute, Bern,
Switzerland

Definition

The IAU (International Astronomical Union) General Assembly officially defined the term planet in resolution 5A (Resolution_GA26-5-

6) in 2006. According to this definition a planet is an object that orbits the Sun, has cleared the neighborhood around its orbit from pre-planetary debris, and has sufficient mass for its self-gravity to maintain a nearly round shape.

Planet Characterization: Emitted and Reflected Light

Pessac, France

Keywords

Transit · Eclipse · Phase-curve · Photometry ·
Scattering · Thermal emission

Definition

A planet reflects light from its host star and emits its own thermal radiation. Even when the planet and its host star cannot be spatially resolved, precise

photometry can be used to extract the planetary component of the unresolved source and constrain properties of the planet and its atmosphere.

Overview

Electromagnetic radiations received from a planet are – as a first approximation – composed of scattered stellar light (“reflection”) and the emission of the planet. Solar system planets being much colder than the Sun these two components are spectrally well separated: the scattered light being in the UV, visible and near-IR range while the emission becomes significant at longer wavelengths, but the scattered and emitted components can significantly overlap in the case of hot exoplanets.

When the image of the planet and its host star cannot be resolved, the light from the planet can be extracted from the spatially unresolved light from the system by different techniques. In transiting systems, the planet periodically disappears behind the star (during the secondary eclipse also called occultation or anti-transit), allowing to measure the stellar contribution and thus, by difference, the brightness of the planet dayside. This can be done in once single spectral band (Deming et al. 2005) or several (Charbonneau et al. 2008). Once the stellar flux is known, assuming it remains constant and that the observation is done with a stable instrument, the change of additional planetary contribution can be followed during its full orbit (Knutson et al. 2009). The variation of this planetary signal as a function of orbital phase is called phase-curve. If observed at wavelengths dominated by scattered light, the phase-curve is maximum at low phases (when the observer is looking at the dayside), decreases to zero toward high phases (when the nightside faces the observer) and constrains the planet albedo. If the observation band monitors mainly the planetary emission, the phase-curve informs on the day-night thermal contrast and more generally on the longitudinal distribution of temperature and therefore on the transport of heat. When several phase-curves are observed in different spectral bands, covering both the reflection and emission domain,

strong constraints can be put on the radiative budget of the planet and the presence and properties of an atmosphere (von Paris et al. 2016).

In practice, stellar variability and limited instrument stability have restricted such observations to hot short-period planets that offer sufficient planet/star contrast. Most measured eclipses and phase-curves are produced by hot Jupiters although it has been observed in the case of a very hot and large terrestrial planet: 55 CANCRI e (Demory et al. 2012).

In multiplanetary systems, individual phase-curves may be entangled making analysis more difficult (Kane et al. 2021).

The modulation of the unresolved star+planet light by the phase of the planet can also be monitored for non-transiting systems but in this case only the variations of the planetary flux can be measured (Selsis et al. 2011).

While broadband eclipse/phase-curves represent the majority of currently available observations, spectroscopy can be performed with the same principles, providing dayside spectra and/or spectral phase-curves carrying more information for characterization (Kreidberg et al. 2014).

High-resolution spectroscopy ($R > 20,000$, able to spectrally resolve single molecular lines, can also be used to extract molecular signatures belonging to the planet from the spatially unresolved star+planet spectrum. To isolate the planetary component, the method uses the Doppler shift associated with the planetary orbital motion and the fact that some molecules are not present in the hot stellar atmosphere. By detecting the water high-resolution signature of the exoplanet 51 Peg b, Birkby et al. (2017) were for instance able to determine the orbital inclination and true mass of the first exoplanet discovered (in 1995). High-resolution spectroscopy requires large ground-based telescopes.

Definition

High-resolution spectroscopy is an observational technique used to detect atomic lines and molecular bands in the atmospheres of exoplanets. It makes use of high-resolution spectrographs mounted on medium to large ground-based telescopes, e.g., VLT-CRIRES, ESO-3.6 m-HARPS, VLT-ESPRESSO, CAHA-CARMENES, TNG-HARPS-N & GIANO, and CFHT-SPiROU. A key advantage of this technique is that it enables atmospheric characterization from the ground by disentangling exoplanet signatures from telluric contamination by Earth's atmosphere. The high spectral resolution (typically $>50,000$) separates spectral features originating in the stellar, planetary, and Earth atmospheres thanks to the different Doppler shifts involved. Moreover, it is possible to combine the signal from many individual spectral lines into a cross-correlation function with increased signal-to-noise ratio. This is particularly powerful for detecting molecular bands made of tens or hundreds of individual ro-vibrational transitions. Detection of chemical species with high-resolution spectroscopy constrains atmospheric composition, chemical abundances, and the pressure-temperature profile. In addition, the study of spectrally resolved line profiles provides constraints on planetary rotation rate, atmospheric circulation (winds), and chemical gradients across the planetary disk. The technique can be applied to transiting exoplanets, in transmission during transit, or in emission and reflected light during secondary eclipse. It can be applied to both transiting and non-transiting planets by following the Doppler-shifting planetary signal in emission or reflected light across different orbital phases.

Various atoms and molecules have been detected in many different exoplanets so far using high-resolution spectroscopy. A few examples are provided below, starting from close-in, massive planets toward cooler, Neptune-like objects. Ultra-hot Jupiters are a recently discovered category of planets whose atmospheric

temperatures are as high as Those of M dwarf stars. As a consequence, molecules are mostly dissociated into atomic species which Are detectable through cross-correlation techniques thanks to their numerous spectral lines, such as Fe (Hoeijmakers et al. 2018; Ehrenreich et al. 2020). Hot Jupiters are somewhat cooler objects that often show prominent bands of CO and H₂O in the near infrared (Snellen et al. 2010; Brogi et al. 2012; Birkby et al. 2013; Alonso-Floriano et al. 2019; Giacobbe et al. 2021; Pelletier et al. 2021). The alkali metals Na and K also have prominent spectral lines in the visible, which have been detected and modeled in several hot Jupiters (Wytenbach et al. 2015; Loudon and Wheatley 2015; Seidel et al. 2020). Finally, the He I transition at 1.08 μ m has recently emerged as a powerful tracer of atmospheric escape in several exoplanets, including Neptune-mass objects (Allart et al. 2018; Nortmann et al. 2018; Pallé et al. 2020).

In the near future, high-resolution spectroscopy will be used to characterize transiting rocky exoplanets, e.g., with the 39-m European Extremely Large Telescope (Serindag and Snellen 2019). Moreover, high-resolution spectroscopy will be combined with high-contrast imaging to characterize terrestrial exoplanets around the nearest stars, such as Proxima b (Snellen et al. 2015; Lovis et al. 2017). This promising new approach has already been demonstrated on the young giant planet β Pictoris b by Snellen et al. (2014). Ultimately, the detection of potential biosignatures such as O₂ and CH₄ in terrestrial exoplanets will be within the reach of the ELT in a few tens of hours of observing time.

Transmission spectroscopy

Definition

The transit of an exoplanet, an event where the planet passes between its host star and an observer, provides a direct measurement of the planetary radius. During the transit, a fraction of the stellar light can be filtered by the atmosphere of the exoplanet. The latest absorbs the stellar flux at specific wavelengths depending on its atomic and molecular composition. The planet is, thus, seen more opaque at specific wavelengths. Therefore, the measured planetary radius changes as a function of the wavelength and results in the transmission spectrum of the atmosphere.

Overview

The atmospheres of exoplanets provide a unique opportunity to better understand the physical, chemical, and evolutionary processes occurring on exoplanets. Information on the atmosphere can be obtained through its transmitted, reflected, or emitted lights, which are sensitive to different layers of the atmosphere. While the reflected and emitted lights probe deeper in the atmosphere (closer to the opaque radius), the transmitted light probes the upper layers from the stratosphere to the exosphere. The transmission spectrum, which expresses the planetary radius variation as a function of the wavelength, reveals the atomic and molecular composition of these layers (Sing et al. 2016), the presence of clouds and/or hazes (Kreidberg et al. 2014), the dynamic of winds (Snellen et al. 2010) but also more complex phenomena such as precipitation (Ehrenreich et al. 2020).

Atmospheric characterization has mainly been done for hot gas giant planets as their atmospheres extend on several scale heights, which corresponds to the change of altitude when the pressure decreases by a factor e , leading to stronger spectral features. These detections have been obtained

through different atmospheric tracers such as H_2O , Na, H, or He. However, the atmospheric characterization of smaller planets remains a difficult task even if the presence of helium has been detected on warm Neptunes (Allart et al. 2018) and the detection of water has been obtained on one temperate mini-Neptune (Tsiaras et al. 2019; Benneke et al. 2019).

Sing et al. (2016) revealed the large diversity of compositions, induced by different physical and chemical processes, for hot Jupiters. They measured the abundance of Na, K, and H_2O but also constrained the presence of diverse clouds and hazes by using a broad spectral range at low spectral resolution. This study reveals how complex exoplanet atmospheres can be, and ask for more observations, and for more in-depth theoretical studies on atmospheric chemistry and the formation of clouds and hazes (Marley et al. 2013).

While the transmission spectrum at visible and infrared wavelengths probes mainly the lower layers accessible through transmitted light, ultraviolet wavelengths are sensible to the outermost layer of an exoplanet atmosphere, the exosphere. It is the region where particles are no more gravitationally bound to the planet and escape into space. Such observations can be done by tracing the hydrogen atoms through the Lyman- α line. The most spectacular result was obtained for GJ436b (Ehrenreich et al. 2015), where a gigantic cloud of hydrogen surrounds the planet, forming a cometary-like tail. Such phenomena can provide crucial information on the formation and evolution of exoplanets. The mass-loss rate of hydrogen for Neptune-size exoplanets could explain the dearth of hot Neptunes (Bourrier et al. 2018).

Linking the lowest layers to the exosphere requires to study the thermosphere. Atomic species such as Na, K, or Fe probe up to the thermosphere and have been extensively studied at high spectral resolution (~ 100000) from the ground. The use of high spectral resolution unlocks the full potential of those lines by resolving them individually. Several studies of these species revealed strong wind dynamics in the thermosphere of hot Jupiters (Wytenbach et al. 2015; Seidel et al. 2019) but also the peculiar chemistry

of the ultra-hot Jupiters (Hoeijmakers et al. 2018). Similarly, the helium triplet at near-infrared wavelengths was revealed as a promising atmospheric tracer to link the thermosphere to the exosphere (Seager and Sasselov 2000; Oklopčić and Hirata 2018). Its recent discovery (Spake et al. 2018; Allart et al. 2018; Nortmann et al. 2018) makes it difficult to have a broader picture but interestingly the transmission spectrum of WASP-107b (Allart et al. 2019) shows two components that can be related to the thermosphere and the exosphere, respectively.

It is also important to note that such lines can be affected by the Rossiter McLaughlin effect. This effect impacts lines present in the stellar spectrum by deforming them due to the partial occultation of the stellar surface by the planet. The most impressive result is for the well-known hot-Jupiter HD209458b (Casasayas-Barris et al. 2021).

The use of different instruments provides complementary information on the study of transmitted light by combining different wavelength ranges but also by using different spectral resolutions. While the low resolution provides a more direct measurement of abundances and constrains clouds and hazes (Sing et al. 2016; Kreidberg et al. 2014), the high resolution provides information on the structure and dynamics of the atmosphere by resolving the lines (Snellen et al. 2010; Ehrenreich et al. 2020). To have a complete view of an exoplanet atmosphere, it is thus necessary to combine multiple atmospheric tracers across the largest spectral range using both low and high spectral resolution.

Upcoming facilities (JWST and the ELTs) will provide first insights into the atmospheric composition of temperate rocky planets such as the Trappist-1 planets (Turbet et al. 2018). Oxygen is foreseen as one of the most promising biosignatures and has the advantage to have strong absorption bands at both visible and near-infrared wavelengths. However, its detections alone will not be proof of life as false positive and false negative scenarios exist (Meadows et al. 2018 and references therein). Nonetheless, by understanding the environmental context of those worlds, we will be able to give more

confidence in the detection of life. Finally, other molecules (e.g., CO₂, CH₄, PH₃) are foreseen as great biosignatures but against the complexity of life, it is necessary to have detections of multiples molecules with the right abundances to claim a robust detection of life on an extraterrestrial world.

Planet Detection: Eclipse Timing Variation

Definition

Planet detection from eclipse timing variations is a method for determining the existence and properties of a planet in an eclipsing binary star system from the gravitational perturbations the planet induces in the orbit of the binary.

Overview

The mutual orbit of an isolated, unperturbed binary star system is purely Keplerian. That is, the two

stars of the binary revolve around their center of mass in Keplerian orbits. In such systems, the orbital evolution of the system can be predicted precisely. If the two stars eclipse each other (in which case the system is known as an eclipsing

binary), the eclipses will happen at the same time and will have the same durations. However, if the orbit of the binary is perturbed, changes will appear in the period of the binary eclipses. This is known as eclipse timing variation or ETV.

Planet Detection: Eclipse Timing Variation, Fig. 1 Gallery of ETV signals due to the LITE found in close binaries KIC 3228863, 4909707, 6265720, 6302592, 6615041, 7339345, 7362751, 8045121, 8043961,

8394040, 8957887, and 9665086. Horizontal axis in days. Typical errors for ETV measurements are shown to the left of the data (Conroy et al. 2014)

Eclipse timing variations may be induced by several processes (Conroy et al. 2014):

1. Light travel time effect (LITE): a third body perturbing the center of mass of the binary system creates a light-time delay along the line of sight which can cause eclipses to appear earlier or later than expected.
2. Nonhierarchical third body: the presence of a third body actually changes the period of the binary over time.
3. Mass transfer: mass transfer between the components in the binary changes the period.
4. Gravitational quadrupole coupling (Applegate effect): spin-orbit transfer of angular momentum in a close binary due to one of the stars being active produces period changes up to

10–5 times the binary period (Applegate 1992).

5. Apidal motion: the rotation of the line of apsides causes a change in the time between primary and secondary eclipses even though the period remains unchanged (requires an eccentric orbit; see Apidal Angle).
6. Spurious signals: due to spots and other effects that distort the eclipsing binary light curve.

Figure 1 shows a gallery of ETVs caused by the LITE.

Using eclipse timing variations to find exoplanets is a well-known method (Schwarz et al. 2011). The idea of photometric detection of extra-solar planets around eclipsing binaries was first presented by Schneider and Chevreton (1990).

Planet Detection: Eclipse Timing Variation, Fig. 2 Graphs of the maximum amplitude of ETVs for three binary models with zero orbital eccentricity. The locations of the bars on the horizontal axis correspond to mean motion resonances (MMR) of 3:1 MMR at 2.1 a_{bin} , 4:1 MMR at 2.52 a_{bin} , 8:1 MMR at 4 a_{bin} , and a

nonresonant case at 6 a_{bin} , where a_{bin} is the semimajor axis of the binary orbit. Graphs are shown for two values of the planet's orbital eccentricity (0 and 0.15). As a point of comparison, the maximum values of detectable timing amplitudes (sensitivity limits) for CoRoT and Kepler (Sybalski et al. 2011) are also shown (Schwarz et al. 2011)

This idea was later developed by many authors (Schneider and Doyle 1995; Doyle et al. 1998; Doyle and Deeg 2004; Deeg et al. 2008; Muterspaugh et al. 2010) and is based on the fact that a circumprimary/circumbinary planet can perturb the orbit of the two stars and create variations in the timing and duration of their eclipses. The measurement of these variations, when compared with theoretical models, can reveal information about the mass and orbital elements of the perturbing planet.

Similar to transit timing variations (TTVs) in close eclipsing binaries, variations in a binary's eclipse timing may be due to a circumbinary planet. The difference between the observed time of mid-eclipse and its theoretically expected (i.e., calculated) value, known as O-C, when determined for different eclipse numbers (or cycles) can be used to extract information about the mass and orbital properties of the perturber (i.e., the circumbinary planet). As expected, when the orbital periods of the planet and binary are commensurate (in the ratio of small integers), the perturbing effect of the planet on the motion of the binary is enhanced. This causes the measured value of the time of mid-eclipse to show large variations from its expected value. As a result, the amplitude of the O-C diagram is amplified when the planet and binary are in a mean motion resonance, making the detection of such planets more practical (Schwarz et al. 2011). Figure 2 shows the maximum values of O-C for different eclipsing binaries with circumbinary planets in different mean-motion resonances.

Planet Detection: Transit Timing Variation

Nader Haghighipour
Institute for Astronomy, University of Hawaii,
Honolulu, HI, USA

Definition

Planet detection from transit timing variations is a method for determining the existence and

properties of a planet from the gravitational perturbations it induces on the orbit of another transiting planet. In an unperturbed planetary system consisting of a star and a planet, the two bodies revolve around their center of mass in a ► [Keplerian orbit](#). If in this system the planet transits the star, it will cross the disk of the star at same time during each transit. As a result, the time of the middle of the transit will be identical every time the planet completes one orbit. If because of some external perturbation (e.g., a second planet), the motion of the transiting planet deviates from purely Keplerian, the time of the mid-transit will be different from one orbit to another. This is known as transit timing variation (TTV). Figure 1 shows this schematically.

Planet Detection: Transit Timing Variation,
Fig. 1 Schematic view of transit timing variation

Overview

The difference between the observed time of mid-transit and its theoretically expected (i.e., calculated) value, known as O–C, when determined for different transit numbers (or cycles) can be used to extract information about the mass and orbital properties of the perturber. This is known as the transit timing variation method of planetary detection. As expected, when the orbital periods of the two planets are commensurate (in the ratio of small integers), the perturbing effect of one planet on the orbital motion of the other is enhanced. This causes the measured value of the time of mid-transit of the transiting planet to show large variations from its expected value. As a result, the amplitude of the O–C diagram is amplified when the two planets are in a ► [mean-motion resonance](#) (Agol et al. 2005; Steffen and Agol 2005; Agol and Steffen 2007). Figure 2 shows this for a three-body system with a 0.367 solar-mass star, a Jupiter-mass transiting planet in a 10-day orbit, and an Earth-mass perturber. The top panel shows the TTVs when the perturber is in a 16.11-day orbit. The bottom panel corresponds to near an interior 1:2 resonance of the two planets (Haghighipour and Kirste 2011). As expected, the amplitude of TTV is enhanced by an order of magnitude. The enhancement of the O–C amplitude when the two planets are in a resonance (i.e., with commensurate orbits) increases the possibility of the detection of these variations. The two outer planets of the Kepler 9 system (Kepler-9b and c) are the first to have been confirmed using the TTV method. These two planets are in a near 2:1 mean-motion resonance (Holman et al. 2010) (Fig. 3).

Because different combinations of the mass and orbital elements of the transiting planet and perturber can produce similar values of O–C, the TTV method suffers from strong degeneracies when used as a mechanism for detecting planets. Several efforts have been made to analyze the O–C diagram and determine the relevant planetary candidates quickly (Nesvorný and Morbidelli 2008; Nesvorný 2009; Nesvorný and Beaugé 2010; Borkovits et al. 2011). Once a region of

Planet Detection: Transit Timing Variation,

Fig. 2 A system with a 0.367 solar-mass star, a Jupiter-mass transiting planet in a 10-day orbit, and an Earth-mass perturber. The *top* panel shows the TTVs when the perturber is in a 16.11-day orbit. The *bottom* panel corresponds to near an interior 1:2 resonance (Haghighipour and Kiste 2011). The amplification of the O–C amplification is by an order of magnitude

the parameter space is identified which can produce the O–C values, other detection techniques need to be employed in order to break this degeneracy. In cases when the free eccentricities of the planets are sufficiently small, TTVs can be used to determine the mass and eccentricity of each planet (Lithwick et al. 2012).

The transit timing variation method has been used to assess the detectability of a variety of systems including extrasolar satellites (Kipping

2009a, b; Schneider et al. 2014), Trojan and co-orbital planets (Ford and Gaudi 2006; Haghighipour et al. 2013), as well as habitable terrestrial planets and super-Earths around a low-mass star (Haghighipour and Kiste 2011).

Recently, the TTV method has been used to determine the masses of the planets of the TRAPPIST-1 system (Gillon et al. 2017). This system hosts seven planets and three of them are in the traditional habitable zone. Knowing the

Planet Detection: Transit Timing Variation,

Fig. 3 Variations in transit times of planets Kepler 9b (blue crosses) and Kepler 9c (red dots) (Holman et al. 2010). The three panels show three different ways of estimating the calculated transit times “C”. Top panel: the calculated transit times “C” were estimated with linear ephemerides (where $C = A + P \cdot t$, where A and P are constants, t is the epoch of transit). Middle panel: the calculated transit times “C” were estimated using quadratic ephemerides. Bottom panel: the calculated transit times “C” were estimated using the outcome of a numerical simulation of the orbital evolution of the two planets with fitted planetary masses and orbits

masses of the planets is important to assess their potential for habitability. The first estimate was performed by Grimm et al. in the year 2018, and it was recently revisited by Agol et al. in 2021 with additional data from the Spitzer satellite (see also the review entry on TRAPPIST-1).

[Accretion](#); [Planetary](#)

Definition

Planet formation is the process by which planetary bodies are formed from a disk of gas and dust around a protostar. Planets can form in two ways. In the regions far from the central star, where the disk can cool efficiently, giant gaseous planets might form as a result of the gravitational instability of the disk; alternatively, these planets may form from the protoplanetary cores discussed below. In the inner regions, planets are expected to form in a more complex, multistage process: first, the dust settles onto the disk’s midplane and coagulates to form asteroid- or comet-like bodies called ► [planetesimals](#). Then, the planetesimals accrete with each other during low-velocity collisions to form *planetary embryos* or *protoplanetary cores*. The former are rocky bodies with masses of the order of the lunar to Martian mass, which form in the hottest region of the disk, where water is not in solid form. The protoplanetary cores, which form beyond the ► [snow line](#), are a mixture of rock and ice and are expected to have multiple Earth masses. These protoplanetary cores then accrete a massive hydrogen and helium atmosphere before the disappearance of the gaseous component of the disk and become ► [giant planets](#). ► [Planetary embryos](#) collide with each other at moderate velocities giving rise to terrestrial-like planets.

Overview

In the ► [protoplanetary disk](#), the most refractory materials condense first, gradually followed – while the local temperature drops – by more and more volatile elements. The dust grains thus formed float in the gas. Collisions stick the grains together, forming fractal aggregates, possibly helped by electrostatic and magnetic forces. Other collisions then rearrange the aggregates and compact them. When the grains reach a size of about a centimeter, they begin to rapidly

sediment onto the median plane of the disk, in a time of the order of 10^3 years. This timescale, however, could be longer if the nebula is strongly turbulent.

The growth from centimeter-size grains to kilometer-size planetesimals is still unexplained. Particles of centimeter size are too small for gravity to be effective in particle-particle collisions but are too big to stick through electrostatic forces. Moreover, grains are subject to ► [gas drag](#), which makes them drift toward the central star (Weidenschilling 1977). The drift speed is size dependent; thus, particles of different sizes must collide with non-negligible relative velocities (of the order of several cm/s). At these velocities, particles should break, rather than coagulate. Because the drift speed toward the central star is maximal for meter-size boulders, this issue is known as the ► [“meter-size catastrophe,”](#) though it is likely that this bottleneck for accretion starts already at much smaller sizes (cm or dm).

One possible solution of this problem is that planetesimals form thanks to the collective gravity of massive swarms of small particles, concentrated at some locations (vortices or intervortex regions, depending on particle sizes) by the turbulence of the disk (Johansen et al. 2007; Cuzzi et al. 2008). This model can explain the formation of large planetesimals (100 km or larger) and the internal structure of these bodies as revealed by the petrology of undifferentiated meteorites.

Once the protoplanetary disk contains a substantial population of planetesimals, the second stage of planet formation starts. The dynamics of accretion is first dominated by the effect of the gravitational attraction between pairs of planetesimals, which increases the collisional cross sections. A ► [runaway growth](#) phase starts, during which the big bodies grow faster than the small ones, hence increasing their relative difference in mass (Greenberg et al. 1978). This process can be summarized by the equation

$$d/dt(M_1/M_2) > 0,$$

where M_1 and M_2 are, respectively, the characteristic masses of the “big” and of the “small” bodies, and can be explained as follows.

Generally speaking, accretion is favored by a high collision rate, which occurs when the relative velocities are large, but also by large collisional cross sections and gentle impacts, which occur when the relative velocities are low. Therefore, the relative velocities between the different planetesimal populations govern the growth regime.

At the beginning of the runaway growth phase, the largest planetesimals represent only a small fraction of the total mass. Hence, the dynamics is governed by the small bodies, in the sense that the relative velocities among the bodies are of the order of the escape velocity of the small bodies, $V_{\text{esc}(2)}$.

This velocity is independent of the mass M_1 of the big bodies and is smaller than the escape velocity of the large bodies, $V_{\text{esc}(1)}$.

For a given body, the collisional cross section is enhanced with respect to the geometric cross section by the so-called gravitational focusing factor:

$$F_g = 1 + V_{\text{esc}}^2/V_{\text{rel}}^2$$

where V_{esc} is the body’s escape velocity and V_{rel} is the relative velocity of the other particles in its environment. Because $V_{\text{rel}} \sim V_{\text{esc}(2)}$, the gravitational focusing factor of the small bodies ($V_{\text{esc}} = V_{\text{esc}(2)}$) is of order unity, while that of the large bodies ($V_{\text{esc}} = V_{\text{esc}(1)} \gg V_{\text{esc}(2)}$) is much larger. In this situation, one can show that the relative growth rate (Ida and Makino 1993) is an increasing function of the body’s mass, which is the condition for the runaway growth.

The runaway growth stops when the mass of the large bodies becomes important (Ida and Makino 1993) and the latter start to govern the dynamics. The condition for this to occur is

$$n_1 M_1^2 > n_2 M_2^2,$$

where n_1 (respectively n_2) is the number of big bodies (respectively small bodies).

In this case, the growth rate of the embryos gets slower and slower as the bodies grow and the relative differences in mass among the embryos are also slowly reduced. In principle, one could

expect that the small bodies catch up, narrowing their mass difference with the embryos. But in reality, the now large relative velocities prevent the small bodies from accreting with each other. The small bodies can only participate in the growth of the embryos. This phase is called ► *oligarchic growth*.

The runaway growth phase happens all through the disk, with timescales that depend on the local dynamical time (Keplerian time) and on the local density of available solid material. This density will also determine the maximum size of the embryos and/or planets when the runaway growth ends (Lissauer 1987). Assuming a reasonable surface density of solid materials, the runaway growth process forms planetary embryos of lunar to martian mass at 1 AU in 10^5 – 10^6 years, separated by a few 10^{-2} AU. Beyond the so-called snow line at about 4 AU for a solar luminosity star, where condensation of water ice occurred thanks to the low temperature, enhancing the surface density of solid material, runaway growth could produce objects as large as several Earth masses, called protoplanetary cores, in a few million years (Thommes et al. 2003). Then, the last stage can lead to the formation of the planets.

Giant Planet Formation

When the protoplanetary cores reach a mass of 5–10 Earth masses, they start to accrete a significant amount of gas from the protoplanetary disk. The gas accretion continues at a roughly constant rate over a few million years, until a total mass of 20–30 Earth masses is reached; then, the gas gravitationally collapses onto the planet: the mass of the planet grows exponentially and reaches hundreds of Earth masses in $\sim 10,000$ years (Pollack et al. 1996). A giant planet is formed.

This model explains well the structure of Jupiter and Saturn, gaseous planets with solid cores of 5–15 Earth masses. It also explains the nature of Uranus and Neptune, ~ 15 Earth-mass planets with only a few Earth masses of gas: these cores would have formed more slowly, given the larger distances to the Sun, so that the gas was removed from the protoplanetary disk before the conditions for the gas gravitational collapse could be met.

There are, however, many conceptual problems with this model. First, although analytic theories predict the formation of 10 Earth-mass cores beyond the snow line, numerical simulations show that the cores have problems to grow above ~ 1 Earth mass (Levison et al. 2010) for various dynamical reasons. Second, planetary cores should undergo a fast orbital migration toward the central star, as a result of their gravitational interactions with the disk of gas (known as “Type I migration”; Ward 1997). Consequently, they should be lost before having a chance to accrete a massive atmosphere and become giant planets. Third, according to theoretical estimates, the conditions for the onset of the gravitational collapse of the gas might not be met before several millions of years (Podolak 2003), a time longer than the typical lifetime of protoplanetary disks (Haisch et al. 2001). Finally, if the gas gravitational collapse takes place, the planet should grow to 5–10 Jupiter masses in a very short time, which makes it difficult to explain the much smaller terminal masses of Jupiter and Saturn.

To circumvent some of these problems, particularly those related to the formation of the cores and their survival in the disk, it has been proposed that giant planets might form directly from concentrations of gas, like a star, without the need of the prior formation of massive solid cores (Boss 2000). In fact, it has been shown that a cold, massive protoplanetary disk can break into a number of self-gravitating gas clumps, which then contract forming giant gaseous planets (Durisen et al. 2007). The key issue is the temperature: as the concentration of gas increases, the temperature rises, which tends to prevent the further accumulation of gas. Thus, the formation of self-gravitating clumps and their subsequent contraction requires an efficient cooling of the gas. For this reason, new hydrodynamical simulations that model more accurately the thermodynamics in the protoplanetary disk find that formation of long-lived self-gravitating clumps of gas is likely only at large distances from the central star (more than 50–100 AU; Boley 2009). It is still unclear, though, whether the end products of these clumps can be giant planets or must be ► *brown-dwarf-mass* objects (Stamatellos and Whitworth 2008).

For all these reasons, the gravitational instability model is now less favored than the core accretion model for the formation of the giant planets of the solar system as well as most extrasolar planets, while it might be an explanation for the origin of massive distant extrasolar “planets” such as those of the HR 8,799 system.

The core accretion scenario, on the other hand, has been recently strengthened by the proposal of a new mechanism for the growth of the solid cores that overcomes the 1 Earth-mass barrier discussed in Levison et al. (2010). According to this new mechanism, dubbed “pebble accretion,” the largest planetesimals which formed from self-gravitating clumps of small pebbles continue to accrete pebbles from the protoplanetary disk (Lambrechts and Johansen 2012). In fact, due to gas drag, most of pebbles passing through the Hill sphere of a growing planet would spiral down to the planetary surface and deliver their mass. Pebble accretion is extremely efficient and fast and potentially can lead to the formation of a 10 Earth-mass core well within the gas disk lifetime.

Terrestrial Planet Formation

The terrestrial planets form from the collisions of the planetary embryos that accreted during the runaway and oligarchic growth phases, in the inner part of the disk. In our solar system, given the presence of Jupiter at ~ 5 AU, the typical result of this highly chaotic collisional phase – simulated with several numerical N-body integrations – is the elimination of all the embryos originally situated in the asteroid belt (2–4 AU) and the formation of a small number of terrestrial planets on stable orbits in the 0.5–2 AU region in a time-scale of ~ 50 –100 My (Chambers and Wetherill 1998; O’Brien et al. 2006; Raymond et al. 2007). This scenario explains the small number of terrestrial planets existing in our system, their orbital eccentricities and inclinations, their accretion timescales determined from the analysis of the radioactive chronometers (Kleine et al. 2009), and their enrichment in volatile elements (including water; Morbidelli et al. 2000) relative to what is expected for planetesimals formed well inside of the snow line.

The main problem of this scenario is that the mass of the synthetic planet formed in the simulations at the location of Mars is typically ~ 5 times too massive (Raymond et al. 2009). Hansen (2009) proposed an original solution to this problem, showing that if the disk of planetesimals and embryos, out of which the terrestrial planets formed, had an outer edge at 1 AU, the large mass ratio between the Earth and Mars is systematically reproduced in the simulations. Mars in this case is an embryo which is rapidly ejected out of the annulus of material by a close encounter with the proto-Earth. Consequently, the accretion of Mars is aborted and the planet can preserve its small initial mass.

The existence of the outer edge of the disk at 1 AU was just an ad hoc assumption in Hansen’s work, but its origin was later explained in Walsh et al. (2011), by invoking the migration of Jupiter during the gas-disk phase. More specifically, hydrodynamical simulations have shown that Jupiter migrates inward while it is “alone” in the disk, but when Saturn reaches its current mass, the presence of this second planet is capable of reversing the migration direction of Jupiter, forcing the latter to move outward. The inward-then-outward migration of Jupiter severely depletes the portion of the disk crossed by the planet. Thus if Jupiter reversed migration (or “tacked”) around 1.5 AU, the disk of embryos and planetesimals would have been truncated at ~ 1 AU, just as required in Hansen’s model. This scenario is now called “Grand Tack scenario.”

Planet V Hypothesis

Sean N. Raymond

Laboratoire d’Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

The Planet V hypothesis proposes that a fifth terrestrial planet (named “planet V”) formed exterior to Mars’ orbit and became dynamically unstable several hundred million years after its formation. This instability could have led to the impact of a large number of asteroids on the Earth-Moon system. The Planet V hypothesis is the main alternate mechanism to the ► [Nice model](#) for the origin of the ► [Late Heavy Bombardment](#).

Definition

The Planetary and Space Simulation Facilities are laboratory devices aimed at mimicking individual or combined extreme environmental conditions as of space (vacuum, temperature, and radiation), or other celestial bodies (atmospheric composition, pressure, temperature fluctuations, and radiation), or moons (gas mixture, pressure, low temperature) for exposure of life forms, e.g., microorganisms, plant seeds, lichens, and organic chemical compounds. They are valuable instruments in the preparation of space experiments and mission parallel ground references (selection of suitable

Overview

In the Planetary and space simulation facilities six recipients and three computer controlled cryostats, three solar simulators, four specialized UV-radiation sources, and a calibrated double monochromator spectroradiometer with calibration source allow a broad range of tests of biological and chemical as well as physical material individually or integrated into space hardware. The close vicinity to molecular biology, genetic, and cell laboratories as well as anaerobic biology laboratories and ISO 8 clean rooms provide the full infrastructure for preflight preparation and postflight analysis of astrobiological and cell biological space missions. The results of these experiments support the design optimization and verification of spacecraft devices, the selection of the most promising biological and chemical material for flight experiments, and the selection of search for life experiments for planetary missions. The following extraterrestrial conditions have been simulated for astrobiology purposes:

- *Simulation of outer space conditions:* Space simulation facilities have been first developed for testing and qualifying space hardware. Test parameters were ultrahigh vacuum, low temperature, extraterrestrial solar ► [UV radiation](#), and X-rays for the simulation of the ionizing component in space. With the increasing interest in astrobiology, these facilities were adapted to expose organics and biological organisms to simulated space (Horneck 1999; Rabbow et al. 2005, 2016). Space simulation

facilities have the common construction principle of stainless-steel cylinders of different sizes equipped with numerous flanges and ports for instrumentation and observation. The main vacuum chamber is connected to different high-performance pumping systems to generate a lowest possible vacuum for the simulation of representative space conditions. A solar simulator, consisting of an array of powerful lamps, reproduces the extraterrestrial solar electromagnetic radiation (from ultraviolet to infrared radiation) at high intensities. Optical filter systems allow the selection of desired wavelength bands and controlled intensities of the radiation. Furthermore, cryogenic systems provide controlled temperatures. Space simulation facilities were intensely used in preparation of the astrobiology exposure experiments in space, such as those using the space ► [exposure facilities](#) on Spacelab 1 and D2, ► [ERA](#) on ► [EURECA](#), Exostack on LDEF, ► [BIOPAN](#) on Foton, and ► [EXPOSE](#) on the ISS (Cockell et al. 2005; Fekete et al. 2005; de la Torre et al. 2007;

Rabbow et al. 2009). They were used as test systems in the preparation of the flight experiments, as well as for the simultaneous ground control experiments (Fig. 1). Similar to the flight parameters of temperature and UV fluences Mission Ground Reference experiments were performed parallel to the respective mission in flight identical sample sets.

- *Simulation of spaceflight (microgravity) conditions:* Various ground-based methodologies have been employed to simulate microgravity for studying its effects on microorganisms, cells, and small biological objects. One of the most common devices used to provide a functional weightlessness is the clinostat. Sedimentation is compensated by fast rotating a small sample centered on a horizontally positioned axis perpendicular to the direction of the gravity vector. Another device is a rotating wall vessel (RWV) bioreactor. While maintaining cells in suspension as they continuously fall through the medium under $1 \times g$ conditions, the RWV bioreactor can also induce a perfusion of nutrients to and waste

Planetary and Space Simulation Facilities, Fig. 1 Overview of the astrobiological planetary and space simulation facilities. Computer controlled and monitored vacuum recipients, cryostats, and solar simulators are combined

from the cell environment. Other approaches for exploring the effect of altered gravity conditions on living systems while still on Earth are free fall, neutral buoyancy, and diamagnetic levitation (Clément and Slenska 2006; Horneck et al. 2010).

- *Simulation of planetary surface conditions:* The evolution of facilities for simulating Mars conditions has progressed over time from very simple anoxic systems to highly sophisticated simulation chambers (reviewed by Hansen 2007). They generally consist of a stainless-steel chamber with control of gas composition, pressure, temperature, and humidity as well as provision of a UV radiation source with optical filters simulating the UV radiation climate of Mars (Schuerger et al. 2003, 2006; Tauscher et al. 2006; Jensen et al. 2008; Osman et al. 2008; de Vera et al. 2010).

Definition

Planetary Ecosynthesis: The purposeful alteration of another planetary environment so as to improve the chances of survival of an indigenous biology or, in the absence of any native life-forms, to allow for habitation of most, if not all, terrestrial life-forms.

History

Terraforming was first used as a word in a science fiction short story in 1942 by Jack Williamson. The first scientific discussion was a suggestion by Carl Sagan, as part of a paper in *Science*, to remove the thick carbon dioxide atmosphere of ► [Venus](#) by seeding the planet with algae. The seminal suggestion to use supergreenhouse gases to warm ► [Mars](#) was made by Lovelock and Allaby (1984) in their science fiction book *The Greening of Mars*. The first technical paper dealing entirely with terraforming was in *Nature* in 1991 by Chris McKay, Brian Toon, and James Kasting, entitled *Making Mars Habitable*. The first discussion of the environmental ethics issues appeared in 1990 in the book *Moral Expertise* in chapters written by Robert Haynes and by Chris McKay. In 1997, the NASA Astrobiology Institute included as one of its six founding questions “What is the potential for survival and biological evolution beyond the planet of origin?” The two international journals *Astrobiology* and the *International Journal of Astrobiology* both include terraforming studies in the scope of papers they publish.

Overview

Terraforming has been discussed for the Moon, Venus, Mars, and Titan (the moon of Saturn). Only for Mars does planetary ecosynthesis appear feasible in the near term. Mars appears to have had habitable conditions in the past, and the fundamental challenge of restoring habitable conditions to Mars is to warm the planet from its current $-60\text{ }^{\circ}\text{C}$ to somewhat over $10\text{ }^{\circ}\text{C}$. Humans have demonstrated the technology to warm the Earth by

a few degrees using greenhouse gases. On Mars, the warming needed would be tens of degrees – many times larger than on Earth. The materials needed to construct a biosphere are water, carbon dioxide, and nitrogen. These are likely to be present on Mars in adequate supply, although there is uncertainty in the total nitrogen available. The fundamental physical aspects of Mars that would be virtually impossible to alter, such as axial tilt, rotation rate, and eccentricity, are similar to the corresponding values for Earth, except for surface gravity, which is 0.38 of the Earth value. If the sunlight incident on Mars was captured with 100% efficiency, it would take only ~ 10 years to warm that planet. Greenhouse gas efficiencies of 10% are plausible, and thus, the timescale for warming Mars is ~ 100 years. In contrast, it would take over 100,000 years to produce enough oxygen on Mars to support humans, and this is based on the optimistic assumption that the efficiency for oxygen production of Mars' biosphere would be the same as Earth's current biosphere. Thus, warming Mars and recreating a thick carbon dioxide atmosphere is within current technology and human timeframes, but creating an oxygen-rich atmosphere is not. Humans would require a source of oxygen, but many microorganisms, some plants, and even a few animals could survive despite the low oxygen content. The practical method to warm Mars involves low levels of supergreenhouse gases composed only of the elements F, S, C, and H. Supergreenhouse gases containing Cl and Br are not used because of the effect these gases have on ozone. If there is enough carbon dioxide ice present in the polar regions of Mars, then a warming of 20°C caused by artificially produced greenhouse gases would cause the complete evaporation of that ice through a positive feedback mechanism. The first ecosystems on Mars would probably resemble alpine ecosystems. A key biological threshold would be the first growth of trees – treeline.

Planets · Solar system evolution

Definition

All solar system bodies (planets, satellites) show an extraordinary diversity in their physical aspect and properties. This entry describes the different physicochemical processes involved in the evolution of a planet, which may be responsible for changes in its internal structure, surface, atmosphere, or magnetosphere, and eventually account for such a diversity.

Overview

From Motion to Evolution

Planets (*vagabonds*, in Greek) have first been recognized and characterized by their apparent movements in space, traveling among the fixed frame of stars. Their motion was proposed as heliocentric by Copernicus and then formalized by Newton; this ended a long, complex, and tough quest, over centuries, with more and more accurate measurements contradicting the dogma of a centrally located Earth. A critical outcome has been that the Earth and the planets belong to the same family. As a consequence, the fact that the Earth has a History and thus evolves implies that all planets do, possibly in a manner similar to the

Earth: worlds' plurality has long been a concept of reference.

However, the prime role of the Sun in controlling the planetary motion and their illumination has erroneously been extrapolated to most, if not all planetary properties: that they would be primarily influenced by the solar gravitational and electromagnetic fields. The planets would thus differ from stars in their lack of energetic means to evolve by themselves: they would essentially simply respond to solar inputs.

Space exploration has dramatically modified this view, in enabling close and in situ analyses of the planets and satellites, which had long remained poorly resolved objects in ground telescopic observations. All these objects exhibit a degree of diversity totally unexpected, and far beyond what could be achieved if the Sun was solely responsible of their evolution.

The state of the four Jovian Galilean satellites, revealed by the NASA/Voyager flybys in 1979, is exemplary of this diversity: these bodies, of similar mass, location, and age, have followed totally distinct evolutionary pathways. Io has been discovered to be a world of extreme volcanic activity, the most intense of the entire solar system: its surface is entirely reprocessed on a timescale of some thousands of years. The surface of ► [Callisto](#) is still saturated with impact craters acquired just after it formed, during the heavy bombardment period; no global resetting seems to have erased this ancient record. ► [Europa](#) is entirely covered with a thick layer of fresh water ice, with a number of crevasses and no craters nor volcanoes. ► [Ganymede](#) is a mixture of rocks and ices, with faults and other features recording past tectonic activity.

The inner planets exhibit similar contrasts. ► [Mars](#) has a few but giant volcanoes, all having ceased to outflow; none are observed on ► [Mercury](#), but thousands on ► [Venus](#). The atmospheric pressure varies from 90 bars at Venus, down to 10 mbars at Mars, and almost zero at Mercury. The cloud coverage varies from none, for Mercury and the Moon, to full, for Venus; the Earth is somewhat in between Venus and Mars, for both its atmospheric pressure and cloud cover. Apart from the Earth, no object, within

the solar system, has been found sustaining liquid water at its surface.

This high degree of diversity strikingly contrasts with the large commonalities in their origin that all solar system objects share: the catastrophic origin of the planets has been definitely abandoned in favor of their being accreted in a single collapsing molecular cloud, formed at the same time (some 4.57 billions of years ago), at the same location in our Galaxy, from essentially the same material. How to account for their differences? What triggers and drives planetary evolution?

It is one of the prime goals of planetary exploration to characterize the specificities of each planet and to derive the clues of their distinct evolution. A central focus is on the Earth, with particular still unresolved questions such as what are the unique conditions that prevailed and still do, which harbored life and maintained its adaptive evolution, up to now? What are the subtle processes at work that sustain the biosphere, with a highly specific ocean and cloud cover? These questions are not of mere curiosity, as our environment changes with an increasingly shortening timescale, now only decades.

To address these questions, as for any dynamical system, one needs to decipher both the *initial conditions* that shaped the planetary evolution, and the *energies* at work all along their history.

Initial Conditions

The initial conditions of planetary formation consist actually in a sequence of processes, over millions to tens and hundreds millions of years.

During its collapse, the protosolar cloud has been subjected to a very specific chemical evolution, ending with a highly complex molecular mixture dominated by H_2 , with abundant H_2O and a wide variety of C-rich species. In particular, large carbon chains were built, giving rise to refractory organics – possibly with chirality trapped in. The cloud was first heated by the energy released while the central core was collapsing, until it reached thermodynamic equilibrium. The p-p thermonuclear chain then started; the Sun, as a star, was born. The emitted radiation blocked further collapse. The cloud started

cooling, and minerals condensed through a sequence primarily dictated by the elemental and molecular composition of the gas. At distances far enough for H_2O ice to become stable, it constituted the most abundant solid phase: the growing bodies accreted predominantly water ice, as a matrix in which most other grains and species, including the organics, were trapped.

The composition of the material subjected to collisions did thus strongly vary with heliocentric distance. Within the inner solar system, minerals were the only solid grains. Slow enough collisions (typically less than hundreds of meters per second) led to accretion of ► [planetesimals](#), some of which accreted further to become planetary embryos; they were essentially anhydrous. At larger distances, water ice started to be stable, first as a minor constituent (>2 astronomical units, AU), then as a major one for >4 AU, typically. Large ice-rich bodies of ~ 10 terrestrial masses grew fast enough to trap and bind gravitationally the surrounding nebula, ending as “giant” gaseous planets. The rapid formation of ► [Jupiter](#), and to a lesser extent of ► [Saturn](#), had a major impact on the further evolution of the entire nebula by the gravitational perturbations they induced, both in the inner and outer parts of the system.

Although this is not fully confirmed yet, Jupiter and Saturn did actually migrate, in a very specific pattern that severely modeled the further evolution of most solar system objects. In this scenario referred to as the “Nice model”, Jupiter migrated inward first, emptying most of the disk from their planetesimals, down about 1.5 astronomical units (AU). Saturn then arrived, at a distance corresponding to a $2/3$ resonance with Jupiter. The mass ratio of these two large bodies prevent them to pursue their inward migration, and made them migrating outward, blocked in this resonance, leaving most of the inner disk confined within 1 AU: its further evolution led to the accretion of the inner planets with their proper mass distribution, characterized by Mars being much smaller than Earth. This accretion was accompanied with inner grains ejected outward, and outer materials injected to the growing inner protoplanets, which led to both repopulating the

asteroidal belt, and feeding the inner planets with water and other volatile compounds. When stabilized close to their present orbit, Jupiter and Saturn gravitational perturbations to objects forming closer and beyond, resulted in stopping their growth, as “small bodies”, which preserve, up to now, the records of these early times. Some of the later, predominantly formed of ices and volatile species, were eventually re-ejected into the inner solar system by later (planetary or stellar) perturbations: their partial sublimation when passing close to the Sun (a few astronomical units apart at most) produces “comae” of gases surroundings their nucleus, thus they are being called ► *comets*.

Thus, the growth of Jupiter and other ► *giant planets* has preserved bodies small enough to have avoided further differentiation, maintaining their pristine composition, in particular in volatile (e.g., H_2O) and organic species. During the early phases of the dynamical evolution of the solar system, collisions played a critical role, in particular when the inner planets, depleted in volatile compounds, were impacted by small bodies formed at larger distances that were thus loaded with low temperature constituents such as ices: this fed the inner planets with large amounts of organics and of water. The terrestrial oceans thus seem to have an extraterrestrial origin. Their seeding with refractory organics might have favored the emergence of biochemistry.

The same process – collisions – which led to planetary accretion for small relative velocities also triggered destruction for large impact velocities (in the kilometer per second range). This explains that the planets and satellites which have, at least partially, preserved the surface structures acquired during the first hundreds of millions of years after they formed are heavily cratered. Actually, some 4 billion years ago, all planets were similarly cratered and looked as most of the Moon and Mercury surface still does. What has differed for planets like the Earth, which no longer exhibits cratered terrains, is their further activity, which erased the records of this ancient bombardment.

The Earth has preserved a key record of its primordial bombardment: its Moon. It is now generally accepted that the formation of the

Moon results from a giant impact of a large embryo, with mass of about 1/10 of that of the Earth, on the proto-Earth. This impact deeply modified the further evolution of the Earth. It melted most, if not all of it, and ejected in a disk a large fraction of the impacting embryo, as well as Earth’s mantle material. Re-accretion within the disk formed the Moon, whose presence still induces important gravitational (tidal) effects. In particular, it prevented the Earth’s obliquity from oscillating around its mean value of 23° by more than 1.5° , which is totally unique in the solar system. Earth has maintained rather steady climatic conditions over its entire history, and this may constitute a key ingredient to the survival of habitable conditions on the Earth, at least for complex organisms. Most of the volatile constituents of the disk fell rapidly back to the Earth. Water in particular was mixed to the outer part of the magma, whose hydration may have eased its convection and contributed to initiating ► *plate tectonics*.

Other planets might have also been subjected to giant impacts. For example, it has been suggested that the present Mars dichotomy, with its northern hemisphere some 15 km below the altitude of the southern terrains, might have been formed in this way; the two small moons of Mars, Phobos and Deimos, could have re-accreted within the circumplanetary disk. However, their very small mass is insufficient to block the chaotic oscillation of Mars’s obliquity, which has driven part of Mars’s climatic evolution.

Did the heavy bombardment steadily decrease over the first half billion years, or was it made of more than one episode? No definite answer is available yet, although several lines of evidences seem to favor the second scenario, exhibiting at least two phases of bombardment. The first one, coupled to the planetary accretion, lasted some tens of millions of years; for the Earth, it included, and possibly ended with the giant impact from which the Moon formed. This bombardment dropped with the decline in the number of potential impactors. Some hundreds of millions of years later, the impact rate suddenly increased, giving rise to a ► *“late heavy bombardment”* (LHB) phase. Its possible trigger is the following: During

their rapid inward, then outward migration, according to the Nice model, Saturn and Jupiter remained in their 2/3 resonance. However, their gravitational interaction with the outer solar system objects, Uranus and Neptune primarily, broke this resonance some hundreds of millions years later, leading to a massive inward ejection of grains and bodies (the LHB), giving rise to a violent bombardment of the inner planets, during tens of millions of years, some 4 billion years ago. A large fraction of the craters, still visible on the Moon, Mercury, and Mars, results from this LHB.

It happens that the migration of Jupiter and Saturn stopped at heliocentric distances larger than 1 AU. This is in striking contrast with the situation found in many other stellar systems, in which giant exoplanets are located much closer to their star, as a result of a much longer migration. The evolution of the Earth and other inner planets would likely have been deeply disturbed if Jupiter had spiraled over them rather than staying at significant distances.

The diversity of our present solar system does not merely originate from the early dynamical history. The composition – elemental, isotopic, molecular, and mineralogical – acquired during the accretion also played a key role. It is remarkable that bodies having preserved records of this primordial composition still exist, enabling its deciphering. This is mainly a result of the specific dynamical history of the protosolar nebula, with the rapid growth of the giant planets inhibiting further growth of comets and asteroids, which remain “small bodies”: with limited energetic content precluding their thermal modification, they still preserve the composition and properties acquired at the time they formed. They constitute objects of utmost importance to trace back the initial conditions of the solar system, from a compositional standpoint. Their characterization can be performed in two ways: by in situ space exploration and, in the laboratory, by analyses of samples either collected and returned from them, or impact ejected from these parent bodies, as meteorites and micrometeorites.

With the highly sophisticated tools nowadays available, most analyses can be performed down to the scale of individual grains. These methods

point out the effects of the isotopic and molecular composition, acquired during the final stages of protoplanetary accretion, on the evolution of the growing bodies. As examples, the “short-lived” radioactive species such as ^{26}Al , trapped together with ^{27}Al in minerals during the condensation sequence, have constituted the dominant energy input at a protoplanetary scale, eventually triggering early mineralogical differentiation of these bodies. Icy grains and hydrated phases, condensed at large heliocentric distances, brought most of the volatile molecules to the inner bodies, including in particular water and complex macromolecules of potential astrobiological relevance.

A fundamental contribution of the isotopic analyses is their enabling of a precise dating of the events that paved the early history of the solar system, within the first tens to hundreds of millions of years following its birth, some 4.57 billion years ago. Some of them are now determined with an accuracy of 1 Ma. One can both identify the processes that were operating within the early solar system and time tag them in a global and accurate cosmo-chronology.

Energy Sources

The sources of energy that sustain activity fundamentally differ between planets and stars. Stellar evolution is essentially driven by the strong interaction, through nuclear reactions triggered by the temperature and pressure produced by the gravitational collapse. At a given point in their life cycle only a few nuclear reactions are enabled, and the stars maintain almost steady global conditions, which allow classifying them in families according to their evolutionary stage. By contrast, all the physical interactions operate for planets, with distinct intensities and time constants, building distinct evolutionary paths and leading to a wide diversity.

The electromagnetic interaction acts predominantly through the solar irradiation. However, photons only penetrate into liquids and solids down to very shallow depths: the solar flux does not contribute to the internal activity. Other electromagnetic effects can operate deep in the planet's interiors, such as phase changes. Whenever gaseous species condense, liquid freezes or

solidifies, energy is released. As examples, the formation of helium rain deep in the atmosphere of giant planets might constitute an important energy input for their evolution. Similarly, the progressive solidification of the outer liquid core within planets releases energy that slows down their transformation.

The gravitational interaction acts through self-collapsing for individual gaseous bodies and through remote interactions for all of them. Tidal effects play specific roles, such as synchronizing rotation and revolution for corotating bodies (planets and satellites). In a few cases, tides may constitute the dominant driver of internal activity. This happens with Io, the closest Galilean satellite, whose strong gravitational lock by Jupiter varies along its elliptical orbit, and is perturbed by Ganymede and Callisto: the energy dissipated deep within Io's mantle produces the highest degree of volcanism within the entire solar system, with plumes some hundreds of kilometers in altitude. Io's surface is entirely remodeled by volcanic outflows on a timescale of a few thousand years.

The weak nuclear interaction is a key provider of energy, through the radioactive decay of isotopes with time constants similar to the age of the planets (10^9 – 10^{10} years typically). Actually, only very few such nuclei exist, and those playing the dominant role are ^{238}U , ^{235}U , ^{232}Th , and ^{40}K . Their relative abundance is low, leading to power release in the order of 10^{-8} W/m³. However, they are present in the bulk of the planetary interior, which makes their input dominate the internal evolution of a variety of planets, in particular of the inner planets, including the Earth.

A specific feature associated with the radioactive energy is its time dependence: as the release is coupled to the transformation of parent nuclei, it necessarily decreases with time. A planet cannot remain in a steady state, as stars do; its activity declines with time. Since the energetic load varies as the volume in which the radioactive species are distributed, while the energy loss operates by surface radiation, the thermal balance depends on the radius. The larger the body, the higher the volume/surface ratio and thus the energy gain/loss ratio, therefore the temperature onset before declining: the later the geological death will occur. This

explains why it happened for the Moon some 3 billion years ago, for Mars some tens of millions of years at most, while the Earth is still active. On the other hand, objects small enough (tens of kilometers in size at most) to efficiently radiate their internal energy have escaped major heating and preserved their primitiveness.

Internal Activity

The internal activity depends both on the available energy and on its transportation throughout the object. For example, the initial gravitational energy load produced during accretion is still partially present in most planets, at least in their core: for the Earth, up to half of the total available energy today might still originate from this early input.

A key feature must be outlined. When the temperature gradient enables convection to operate, sustained motions of matter take place, possibly up to the surface: the object is active.

Mineralogical differentiation under gravity precipitates the denser materials downward, leaving the lightest ones toward the surface. A high density (~ 8) solid core forms, constituted of metal-rich compounds, dominated by Fe/Ni alloys; it is possibly surrounded by a liquid envelope of similar elemental (metallic) composition. If turbulent convection in this outer liquid core occurs, a dynamo is generated: the planet develops a global magnetic field.

Above the core, a mantle of fused rocks exists, covered by a light crust. As the temperature decreases toward the surface, both the upper part of the mantle and the crust are cold enough to be solid, constituting a *lithosphere* (Greek for “sphere of stones”); the inner part of the mantle down to the core is sufficiently warmed to be fluid, thus it is called an [asthenosphere](#), swept by convection movements. Upwelling flows of magma slowly solidify as rigid plates as they approach the surface, and then drift horizontally at a velocity of some centimeters per year. They thicken by cooling, until their mass forces them to sink back to the mantle, at *subduction* zones. This latter movement is severely constrained and proceeds by pulses capable of generating earthquakes and tsunamis.

These convective cells drive the global planetary internal activity, known as *plate tectonics*. In the case of the Earth, most of these plates are covered with oceans. The remaining ~30% are covered with continents, which are thus carried in the drift of the plates. As the continents are made of material less dense than the underlying floor, they remain at the surface and stay blocked over the subduction zones, where they eventually collide with a continent moving counterward: the shock results in mountains and faults.

This geological evolution typically operates over timescales of tens to hundreds of millions of years. With the slow decrease of internal energetic resources, and the correlated thickening of the outer rigid layer, the planet approaches its geological death: it occurs when its surface becomes no longer affected by the internal activity. Only exogenous and atmospheric processes may further drive their evolution.

Atmospheric Evolution

The planetary atmospheres evolve both in composition and density, with timescales ranging from long-term variations to seasonal changes. As an example, the present-day terrestrial atmosphere, with a pressure of one bar dominated by N₂ (78.9%) and O₂ (20.1%), differs from the early one in at least two respects: most of the CO₂, whose pressure amounted to tens of bars (as is still the case for Venus), have been dissolved and trapped into carbonates, thanks to the sustained presence of stable oceans, leaving N₂ the most abundant species; on the contrary, most of the present O₂ appeared long after the planet formed. It results from the photosynthetic activity of living organisms, as an outcome of their building C-rich molecules from CO₂. Both these changes operated over hundreds of millions of years. By contrast, a huge enrichment of the amount of CO₂ is observed nowadays, with timescales of decades, most likely as a result of human activity – most energy is produced through the combustion of C-rich molecules (oil, coal, wood).

Importantly, the atmospheric content in major, minor, and trace elements does depend on the planet's internal activity, in at least two ways: through outgassing mostly coupled to volcanic

activity and through plate tectonics. For example, a fraction of the CO₂ originates from the dissociation of carbonates within continents reaching subduction zones. As such, the radioactive energy plays a key atmospheric – and thus climatic – role in sustaining the recycling of key species, as discussed below for greenhouse gases.

However, by far the dominant energy source that drives atmospheric processes originates from the solar irradiation. The radiation transfer is highly dependent on the composition of the atmospheric constituents: gases, clouds, ices, aerosols, and grains. A complex photochemistry takes place, thermodynamically constrained, resulting both in a layering of the atmosphere and in its movement, with circulation loops at different scales.

These interactions translate into a specific thermal profile of the atmosphere, well described in the case of the Earth. The temperature profile exhibits three *inversion* layers (inversion of the sign of temperature vertical gradient). From the surface upward, the temperature slowly decreases within the *troposphere*, mostly heated by contact with the surface. At some 20 km in altitude, the thermal gradient becomes positive: in the overlying *stratosphere*, the temperature increases, through the absorption of ultraviolet (UV) solar photons. O₂ is dissociated and the freed O atoms, reacting primarily with O₂ and N₂, form ozone (O₃) and a variety of N-rich molecules, blocking all the UV solar photons. The stratosphere thus shields the troposphere against the lethal effects of these high-energy photons. The upper limit of the stratosphere (~40 km) is defined by the pressure above which the cross section for the O₂ photodissociation becomes marginal (the pressure is too low): in the absence of photon absorption, the temperature thus decreases with altitude in the *mesosphere*, as it does in the troposphere. At still higher altitudes (~80 km), solar X-rays are absorbed and ionize the atoms: the top atmospheric layer above the mesosphere is accordingly named the *ionosphere*.

Consequently, the incoming solar flux is progressively depleted in its high-energy photons (X, UV), in the ionosphere and then the stratosphere, before entering the troposphere, where the visible

wavelengths (0.4–0.8 μm) dominate. The photons that are not reflected (mostly by the clouds and the surface ice) are absorbed on the ground. They are then reemitted with a distinct energy distribution, imposed by the surface temperature, which is some 20 times lower than that of the solar photosphere: their spectrum covers primarily the infrared (IR) range, according to Planck's law. Minor constituents of the terrestrial atmosphere, such as H_2O and CO_2 , have no transition in the visible, but strong vibration modes in the IR: they are transparent to the incoming solar flux, but highly absorbing for the radiation emitted by the surface at longer wavelength. They constitute very efficient *greenhouse* gases responsible for an increase in the Earth's surface temperature of $\sim 33^\circ$. More generally, the surface temperature of a planet, in particular with respect to water stability, does not merely depend on the solar influx, but also on its atmospheric composition, in particular with respect to its content in greenhouse gases.

The orbital evolution of the planets has strong effects on their level of insulation. Over the year, the total amount of solar energy received varies with the distance to the Sun, with larger variations for more eccentric orbits. In addition, the insulation depends on the obliquity, defined as the angle between the planetary axis of rotation and the orbit plane – known as the ecliptic. The Earth is closer to the Sun in early January; it receives some 6% more energy in northern winters than in northern summers which, given the distribution of continents and oceans, contributes to damping the global annual temperature variations. This configuration changes over time, as the axis of rotation spins with a period of some 25,000 years (precession of the equinoxes). Actually, all orbital parameters vary with time, which induces variations of most climatic parameters, primarily of the temperature distribution with average amplitude changes of some degrees. This is the major driver of the recurrent glaciations, as first demonstrated by Milutin Milanković.

An important factor that dictates the temperature of the lower atmosphere is the cloud coverage, which strongly differs from one planet to the next. The cloud $\blacktriangleright$ [albedo](#) is high enough to reflect a large fraction of the incident solar flux:

terrestrial cumulus clouds block up to 50% of the incoming energy. Has their coverage changed with time, which would have led to significant variations of the global averaged temperature? Actually, a definite answer cannot be given yet, since cloud formation results from a rather complex suite of processes, involving still unknown nucleation sites on which water or other molecules condense, if enabled by thermodynamics. This microphysics remains an era of deep studies, with potential major outcomes for the present climatic change operating on Earth: clouds, which have a greenhouse effect given their composition, are also cooling agents by reflecting a fraction of the incident solar input, thus decreasing the energy available at lower altitudes. The potential for part of the water, which increasingly evaporates from the oceans as the temperature rises, to condense as clouds might thus constitute an efficient retroactive means to control the global temperature.

Altogether, the evolution of planets result from a highly complex coupling of processes involving all forces, with often key roles played by minor or trace species, such as long-lived radioactive isotopes for the internal activity, greenhouse gases for surface temperatures, and nucleation sites for cloud formation. The early dynamical evolution has paved the entire solar system history with unique properties.

The more we observe and decipher this complexity, the more we realize that the diversity we discover does not result from observational biases, but rather constitutes a key feature of planetary evolution.

Planetary Mapping

Giulia Alemanno
Institute of Planetary Research, German
Aerospace Center, Berlin, Germany

Keywords

Planetary surfaces · Mapping · Geologic maps

Definition

Planetary mapping is the process of creation of geologic and geospatial maps of surface features of planetary and small bodies surfaces based on the current state of discoveries and knowledge. Planetary maps are created based on the use and analysis of several orbital data sets, so they evolve continuously with time thanks to new discoveries and to the use of new orbital data.

Overview

Planetary mapping involves geologic, imaging, and geospatial mapping of planetary surfaces structures, materials, and landforms. These maps provide a contextual framework for the study and interpretation of the history of planetary surfaces and their evolution through time. Planetary maps are usually composed by at least three layers: a base image (that can be for example a photomosaic or a topographic mosaic of the bodies surfaces); a grid; and a nomenclature (Hargitai 2006). Geologic maps of planetary bodies surfaces are a powerful tool for the scientific community for several reasons. Those maps contribute to the investigation of processes that characterize planetary surfaces and their shallow subsurfaces, thus

allowing to reconstruct geologic timescales and to provide an interpretation of the sequence of events that characterized the evolution of a planetary surface. Surface geologic maps are also used for target investigations such as those based on the characterization of landing sites for lander/rover missions. At the same time, planetary maps can be created using tools that target the general audience thus involving their interest to the scientific discoveries regarding the other worlds that surround us.

The US Geological Survey (USGS) started to publish planetary geologic maps in 1962 (Hackman 1962). So far, several maps of planetary bodies have been published (e.g., Hansen 2000; Grant et al. 2009; Irwin III and Grant 2013; Alemanno et al. 2018). Planetary bodies have been mapped at a variety of scales, using the available topographic and photographic orbital data. An international overview catalogue containing over 2200 planetary maps produced worldwide between 1600 and 2018 has been published from Hargitai and Pitura (2018). However, the production of maps of planetary surfaces is a continuous effort: new data are continuously acquired from the planetary bodies of our Solar System at increasing resolution providing the basis for new discoveries and updated geologic maps.

[Tidal migration](#)

Definition

Planetary migration is the decrease or increase in the orbital radius of a planet embedded in a ► [protoplanetary disk](#) due to interactions with the surrounding gas and/or solid material. Migration occurs when a planetary body loses or gains orbital angular momentum due to either friction (either through aerodynamic drag with the surrounding gas or dynamical friction with surrounding smaller planetesimals) or the imbalance of momentum transfer between the planetary body and the nearby disk material. Planetary migration is thought to account for the position of giant extrasolar planets discovered orbiting at very

small orbital radii and may be an important dynamical process in the evolution of protoplanetary bodies of all sizes.

Overview

Prior to the discovery of the first extrasolar planets orbiting very close to their parent stars, planets were thought to form and evolve in the same general region of a planetary system over their whole lifetime (unless a planet's orbit was dramatically altered due to scattering from a close encounter with another planetary body). Small planetesimals would grow into larger bodies by accreting nearby material, and accretion would stop when a planet had depleted its local orbital region of material. In this relatively quiescent picture of ► [planet formation](#), a mature planet found at a specific orbital radius could be assumed to have formed in situ from a collection of smaller bodies with similar compositional properties.

However, the existence of giant planets at small orbital radii immediately confounded the idea that all planets form and remain in their initial orbital locations. Giant planets are composed primarily of a massive gaseous atmosphere and for the atmosphere to gravitationally contract the planet must form in a relatively cold region of the disk (beyond ~ 3 AU; Bodenheimer et al. 2000). The first extrasolar planet, a Jupiter-mass planet orbiting at 0.04 AU, therefore, suggested that some mechanism must have transferred the planet from the outer regions of the system to its current location.

The theory of planetary migration had been postulated prior to the discovery of close-in extrasolar planets; in fact, dynamical theorists might have predicted the existence of these planets if they had correctly interpreted their results on the evolution of giant planets embedded in viscously evolving protoplanetary disks. Papaloizou and Lin (1984), and Lin and Papaloizou (1986), first showed that a planet with a mass significantly large with respect to a surrounding gaseous nebula could open a gap in the disk, leading to angular momentum transfer between the inner and outer regions of the disk and the planet. They correctly

showed that this would lead to orbital migration of the planet if the difference in mass between the two regions of the disk was significant; the authors, therefore, concluded that the amount of nebular gas interior and exterior to Jupiter's formation region in our own Solar System must have been equal to $0.1 M_{\text{Sun}}$ in order to avoid the rapid migration of Jupiter either inward or outward. This mechanism for planetary migration, eventually codified as "type II" gas-driven migration by Ward (1997), was immediately posited as the process responsible for transporting extrasolar giant planets to very small orbital radii (Lin et al. 1996).

In the next paragraph, we will discuss the various theoretical mechanisms for orbital migration in a circumstellar disk of planetary and protoplanetary bodies, ranging from giant planets down to micron-size dust particles, and the current evidence for the role that each process plays in the evolution of a planetary system. Please note that there exists another type of orbital migration due to tidal interactions between a star and planet (see ► [Tides, Archean](#)).

Migration Mechanism

Gas-Driven Migration

Gas-driven migration refers to a loss of orbital angular momentum from a planet due to gravitational interactions with the gaseous disk. This mechanism is the most common process referred to when discussing planetary migration, due to the early adoption of gas-driven migration as the most

likely scenario to explain the existence of close-in extrasolar planets. As the name suggests, type II gas-driven migration was not actually the original form of gas-driven migration proposed. "Type I" gas-driven migration, first theorized by Goldreich and Tremaine (1980) and discussed in more detail by Ward (1986), operates on planets whose mass is low enough (thought to be close to the mass of Saturn for a disk around a solar-type star) to avoid perturbing the disk enough to open a gap. Type II gas-driven migration describes a similar mechanism for higher-mass planets which perturb the disk enough to block the infall of gas toward the star and create a gap, leading to the locking of the planet with the viscous evolution of the disk (i.e., the spiralling in of the disk material onto the central star) (Fig. 1).

Type I Gas-Driven Migration

Type I gas-driven migration relies on the torques exerted on a planet from density waves that are excited in the gaseous material close to the planet's Lindblad resonances (the orbital locations relative to a planet where the orbital period of a satellite around the planet equals the orbital period of the planet around the star, leading to a resonant orbital motion). These density waves remove energy from the planet, which can lead to a decrease in the orbital velocity and an inward migration. The originally calculated timescale for an Earth-mass body to fall into the central star from 5 AU due to type I gas-driven migration was $\sim 10^4$ years, making this process the most rapid migration mechanism acting in

Planetary Migration, Fig. 1 Results from simulations of gas-driven migration, showing the disk density for a planet that is unable to open a gap and therefore experiences "type I" migration (*left*) compared with a high-mass planet that clears a gap and experiences "type II" migration (*right*). (Source: Armitage and Rice 2005)

protoplanetary disks and a huge problem for the survival of planets, since the lifetime of a gaseous protoplanetary disk is $\sim 5 \times 10^6$ years. The rate of type I migration increases with increasing planet mass until the planet reaches the gap-opening threshold.

Research is ongoing to determine how type I gas-driven migration is slowed (it must be slowed since we observe planets the size of Earth and larger in both our own Solar System and other planetary systems, so they must survive). Initial models for calculating the migration efficiency assumed a very simplistic version of a protoplanetary disk: no turbulence, no temperature variations, constant viscosity throughout the disk, etc. Many different theories are being explored that rely on more realistic details of the disk conditions and structure to decrease the migration rate, and it is currently unclear which slowing mechanisms are dominant in different disk conditions. The most promising theories focus on non-isothermal conditions near the planet and the resulting effects on energy transfer (Jang-Condell and Sasselov 2005; Paardekooper and Mellema 2008), and inclusion of turbulence (e.g., Laughlin et al. 2004) and investigations of “dead zones” in the disk where the disk viscosity drops to near zero, leading to a dramatic decrease in the energy transfer rate between the planet and the disk (Oishi et al. 2007). In recent years, large progress has been made in the determination of the planetary migration rate, for different thermodynamical properties regimes in the protoplanetary disk (Paardekooper et al. 2011).

Type II Gas-Driven Migration

As stated above, the mechanism known as type II gas-driven migration becomes important when a planet becomes large enough to be comparable with the scale height of the disk, causing all the material in an annulus around the star to either be accreted onto the planet or transferred out of the orbital region by mass transfer to the outer disk. Once the annulus is cleared, no material is transferred across the boundary, but the planet is still gravitationally pulled toward a faster orbital velocity by material from the inner disk, while

losing angular momentum to material in the outer disk. If the outer disk is more massive, this transfer of angular momentum is imbalanced and the planet loses energy and spirals inward. Since the planet is locked to the viscous evolution of the disk, it migrates at a rate unrelated to the mass of the planet; two-dimensional and three-dimensional simulations suggest timescales of $\sim 10^5$ years for the migration time from 5 AU (D’Angelo et al. 2003).

This timescale is still shorter than the dissipation of the disk, and therefore a stopping mechanism must be invoked to stop planets from falling into the central star. Initial stopping mechanisms invoked interactions with the central star to explain the origin of close-in giant planets – either a removal of disk material by some process such as magnetospheric clearing or photoevaporation, or tidal interactions with a rapidly rotating star (Lin et al. 1996). However, these mechanisms are only applicable at very small distances from the parent star. For planets from 0.1 AU out to 3 AU, there must be either a different stopping mechanism or a different migration mechanism at work. The explanation of last resort has always been the “last of the Mohicans” argument, which suggests that the only planets we see are the last ones to migrate in and become stranded when the disk finally dissipates (Trilling et al. 1998). However, the currently favored explanation is that when two or more planets form in relative proximity in time and orbital radius, they can quickly migrate into a resonant relationship (such as the 3:2 ► [mean-motion resonance](#)), at which point their gaps can overlap and cause them to cease migrating or even reverse their migration direction (Morbidei and Crida 2007; Morbidelli et al. 2007). This explains the lack of a close-in extrasolar planet in the Solar System, while leaving considerable parameter space for a wide range of planetary configurations. In addition, planetary systems with more than one planet can become unstable after the gas disk dissipates, scattering one planet out of the system and leaving only a single remaining giant planet in an eccentric orbit – a scenario observed frequently in extrasolar planetary systems.

Migration Due to Aerodynamic Drag

Gas-driven migration is effective for both giant planets (type II) and Earth-mass planets down to km-sized bodies (type I), but the gaseous disk also leads to migration of very small planetesimals ($r < 1$ m) due to aerodynamic drag. First analyzed with respect to protoplanetary disks by Adachi et al. (1976), frictional drag due to a particle's motion through the gaseous disk can lead to eccentricity and inclination damping and inward radial migration on timescales as short as 100 years from 1 AU for cm-sized particles. For smaller particles, the grains become entrained with the gas and their differential velocity decreases; for larger particles, the aerodynamic drag force is too small to affect the angular momentum of the body significantly.

Drag forces can help to enhance the growth of bodies as a result of accretion, by damping collisional velocities between particles, but this would be of no consequence if particles were quickly lost into the central star on 100-year timescales. This problem is called the “cm-sized barrier,” connoting the difficulty of growing planetesimals beyond this limit, since traditional collisional accretion timescales for expected particle densities are much longer than 100 years. Possible solutions to this problem include rapid planetesimal growth due to gravitational instabilities, which have recently been shown to form km-sized bodies from pebbles over the course of 5–10 orbital timescales (Johansen et al. 2009), as well as phenomena that could cause pileups of inwardly drifting material in the disk, such as condensation fronts (Stevenson and Lunine 1988). Radial migration of small bodies due to aerodynamic drag may also have had a beneficial effect on planet formation and habitability by delivering volatile-rich bodies from the outer solar system into the dry inner disk, leading to increased water contents for the terrestrial planets (e.g., Ciesla and Cuzzi 2006).

Planetesimal-Driven Migration

Planetary migration can also be achieved without the need for a gaseous disk. Loss of angular

momentum from a planet can be achieved by transferring it to smaller nearby solid bodies during a scattering event. First suggested by Safronov (1972), the mechanism was first modeled numerically by Fernandez and Ip (1984) for giant planets in the Solar System, and the outward migration of Neptune due to the scattering of outer-disk planetesimals can be traced by mapping the scattered and resonant ► [Kuiper Belt](#) objects (e.g., Malhotra 1993). More recently, inward migration of the giant planets in the Solar System due to planetesimal scattering was invoked to explain the Late Heavy Bombardment as a critical aspect of the ► [“Nice model”](#) (Gomes et al. 2005). According to the Nice model, Jupiter and Saturn would slowly have migrated inward due to the migration instability, eventually crossing into a mean-motion resonance which pumped up their eccentricities dramatically, leading to a chaotic reshuffling of the outer Solar System.

The planetesimal-driven migration instability has also been suggested as an important migration mechanism in extrasolar planetary systems (Murray et al. 1998). However, in order to move a Jupiter-mass planet from the outer system all the way to within 0.1 AU of the star, a disk with approximately 1 Jupiter mass of planetesimals would be required interior to the planet's original orbit. This would require a massive disk ($\sim 0.1 M_{\text{Sun}}$), and while this is not impossible, it would be unlikely to be responsible for the bulk of migration in extrasolar planetary systems.

Planetary Nebula

Nikos Prantzos

Institut d'Astrophysique de Paris,
Paris, France

Definition

A planetary nebula is the glowing shell of gas, typically one light-year across, ejected during the late AGB phase of intermediate and low mass stars. The name derives from the appearance in a small telescope, similar to that of a planet. It surrounds the hot, luminous core of the star, which emits ultraviolet radiation and ionizes the gas. The planetary nebula phase lasts for only a few 10^4 years, after that the star (the future ► [white dwarf](#)) is no longer hot enough to ionize the gas. This material eventually dissolves in the interstellar medium, enriching it with the nucleosynthesis products of the parent star (He-4, C-12, N-14, and ► [s-process](#) elements). The number of planetary nebulae in the Galaxy is estimated at 3,000.

Backward contamination · Contamination control · Forward contamination · Life detection · Sample return

Synonyms

[Planetary quarantine](#)

Definition

Planetary Protection is the process of preventing contamination of planetary environments by living organisms from other planets, in accordance with Article IX of the 1967 Outer Space Treaty and policies maintained by the Committee on Space Research (▶ [COSPAR](#)). Nations sending missions to other planets must ensure that Earth life does not contaminate them (forward contamination), and that any samples brought to Earth do not release harmful organisms into our environment (backward contamination). Protecting the Earth is the highest priority for planetary protection. Protecting other planets from Earth life preserves our investments in scientific exploration and the search for life elsewhere.

Overview

Planetary protection requirements are based on the type of planetary mission and target location

(s), according to Categories defined in COSPAR policy. The lead agency for a mission is responsible for ensuring compliance by all participants with planetary protection requirements, and reporting to COSPAR on mission activities.

▶ [Mars](#), ▶ [Europa](#), and ▶ [Enceladus](#) are Solar System objects considered to have the highest probability for hosting Indigenous life, and for contamination by transported Earth life. The probability of contaminating these objects with Earth life must be less than 1×10^{-4} per mission. Missions to Mars are allowed to meet this requirement by limiting the number of ▶ [“spores”](#) contaminating the spacecraft at launch, based on calculations performed by ▶ [NASA’s Viking](#) project in the 1970s. Missions that search for life, either in situ or in samples returned to Earth, must ensure that samples being analyzed are not contaminated by ▶ [biomarkers](#) from Earth life. A high-confidence life detection event would impose more strict cleanliness requirements on subsequent missions, so minimizing “false positive” results is required by planetary protection. To protect the environment of the Earth, any samples that are returned to Earth from objects that might host Indigenous life (e.g., ▶ [Mars Sample Return](#)) must be contained similarly to the most infectious human pathogens, until they have been demonstrated to be non-hazardous. A “false negative” result could increase risk to the Earth, if unidentified extraterrestrial organisms are subsequently released.

Missions encountering only targets that cannot host Earth life are not required to limit ▶ [bioburden](#), but mission operations and disposition of hardware must be documented. Missions encountering objects of interest for understanding prebiotic chemistry and the origins of life (e.g., Venus, the Moon) must retain samples of all organic materials carried on the spacecraft in quantities that might be detectable by future missions.

Planetary protection requirements for human missions are still being developed but must meet the same goals of preventing forward and backward contamination. However, it will not be possible to prevent astronauts from being exposed to planetary materials, nor is it possible to ensure that no Earth life is released into a planetary

environment. Thus, constraints on human missions focus on understanding what Earth organisms are present on the mission and how they change over time to affect astronaut health, as well as minimizing and documenting cross-contamination between terrestrial and other planetary materials.

Definition

Individual missions are assigned a ► [planetary protection](#) category based on the type of mission (flyby, orbiting spacecraft, landing probes) and the target object that the spacecraft will investigate. The categorization system is used to set requirements based on the level of concern

regarding the possibility of contaminating a target object by Earth life, as well as the possibility that returned samples might contain extraterrestrial life, as specified in ► [COSPAR](#) planetary protection policy. The possible assignments include missions that target locations of no concern for contamination by Earth life and no relevance to investigations of prebiotic chemistry (Category I), missions to locations where Earth life could not survive but there is interest in studying possible prebiotic organic chemistry (Category II), and missions that target locations where Earth life could survive and reproduce (Category III for flybys and orbiting spacecraft, Category IV for landing probes). All missions that return samples to Earth are assigned to Category V but only missions returning samples from locations that might host indigenous life (e.g., ► [Mars](#), ► [Europa](#), ► [Enceladus](#)) are designated Restricted Earth Return and have additional restrictions beyond those imposed on the outbound portion of the mission.

Definition

Planetary rings are systems of dust, particles, and small satellites orbiting around the ► [giant planets](#) of the solar system, in the nearby vicinity of a planet, where large satellites cannot form because of tidal effects.

Overview

Before observations were possible, the ancients imagined that stars were similar to the Sun and were surrounded by exoplanets, but no one imagined the possibility of planets surrounded by rings. In fact, all the giant planets are surrounded by a ring system located close to the planet. Giant planets own also large and regular satellites with prograde and circular orbits and, farther away, irregular satellites with orbits possibly retrograde and/or inclined.

The first telescope allowed Galileo Galilei to observe in 1610 that ► [Saturn](#) has a strange shape, which changed in course of time. It was only 46 years later that Huyguens (1656) proposed that “Saturn is surrounded by a thin flat ring, nowhere touching and inclined to the ecliptic.” This correct interpretation of poor-quality observations was based on the philosophical model of Descartes that a vortex is a natural shape in the Universe. It was only in 1857 that theoretical considerations led JC Maxwell to conclude that the ring is composed of small orbiting particles and not a solid ring, as initially thought.

In 1977, the ► [occultation](#) of a bright star by ► [Uranus](#) was observed by Elliot and his colleagues to study the planet’s atmosphere. The star disappeared very briefly nine times before and after the occultation by the planet, revealing Uranus’ ring system. This was the discovery that Saturn was not the only planet to be surrounded by rings and that narrow planetary rings can be stable. Subsequently, Goldreich and Tremaine (1982) showed that gravitational interactions between ring particles and nearby satellites can account for narrow and eccentric rings. This shepherding mechanism is one of the numerous and complex phenomena due to ring-satellite interactions.

The next ring was discovered around ► [Jupiter](#) by a space mission, Voyager 1, in 1979. This third ring system is very different from the first two; it is broad and ethereal, a million times less opaque than the dense Saturn rings. The dust particles, governed by nongravitational forces, have short lifetimes and must be permanently resupplied by moons. Dusty rings exist in the four planetary systems and are associated with satellites.

The last giant planet hid its ring system until 1984. Again, it was a stellar occultation that revealed a ring structure around ► [Neptune](#) (Hubbard et al. 1986). This discovery included another surprise, as the ring was detected on one side of the planet but not on the other side, showing an incomplete ring. An intensive campaign of stellar occultation observations revealed that one-tenth of the ring length is denser than the rest. This was confirmed when Voyager 2 imaged, in 1989, three dense arcs embedded in dusty ethereal rings. From this time, the three arcs have evolved to four arcs, two of which have partially vanished, showing the short lifetime of these structures. Resonances with moons on eccentric and/or inclined orbits explain the stability of incomplete rings. However, recent observations found that the arcs are not at the position predicted by the theory, leaving a puzzling situation.

The four ring systems and embedded satellites are described in Fig. 1. Particle characteristics are summarized in Table 1. The Saturn system is composed of five rings, with most edges confined by observed satellite resonances. In the ethereal Jupiter system, a 1,000-km wide region between the Adrastea and Metis orbits could be the location of invisible (smaller than 0.5 km) bodies, “parents” of dusty rings. Shepherding by satellites of the narrow Uranus rings and the Neptune arcs is not yet completely explained.

Basic Methodology

Observations from ground and from space (survey and orbiter missions) of the last 50 years have led to a good knowledge of the ring systems. After Pioneer surveys of Jupiter and Saturn, Voyagers I and II in the 1980s explored the four systems and

Planetary Rings,

Fig. 1 A comparison of the four planetary ring systems, including the nearby satellites, scaled to a common planetary equatorial radius. Density of cross-hatching indicates the relative optical depth of the different ring components. Synchronous orbit is indicated by a *dashed line*, the Roche limit for a density of 1 g cm^{-3} by a *dotted line* (From Esposito 2006)

led us to the current conception of young and dynamic rings. The Cassini orbiter is now in orbit around Saturn after having flown by Jupiter. Evolution in ring structures can also be monitored from the ground, thanks to high-angular-resolution observations. Special events such as stellar occultations and ring-plane crossings provide unique information on the ring structures and particle sizes.

N-body simulations with tens of thousands of particles, taking into account mutual gravitational forces, can simulate formation of viscous instability, collective wakes, and accretion phenomena (Salo 2001). The rings and their evolution can

also be fruitfully simulated as fluid (hydrodynamics) or gas (kinetic theory).

Planetary rings are a laboratory where dynamic mechanisms including waves, wakes, braids, clumps, confinement, or migration are observed and studied at all scales (Fig. 2). These mechanisms are certainly involved in other astrophysical disks, such as occur in galaxies, accretion disks, protoplanetary disks, disks of second generation, etc.

The natural evolution of colliding particles orbiting around a planet is to aggregate into a satellite because of inelastic collisions. However, within the Roche limit (D_R) of

Planetary Rings, Table 1 Planetary rings characteristics (From Esposito 2006)

	Planetocentric distance (width) (km)	Optical depth	Dust fraction (%)	Power-law index (particle size distribution)	Notes
Jupiter					
Halo	92,000–122,500	10^{-6}	100	?	12,500 km thick

Lasell	53,000–58,000	$1-3 \times 10^{-4}$	?	?	
Adams	62,930 ($W = 50$ km)	10^{-2}	2–50	?	Adjacent to Galatea
Adams arcs	62,930 ($W = 10$ km)	10^{-1}	4–70	?	

$$D_R = 2.456 * R \left(\frac{\rho_P}{\rho} \right)^{1/3}$$

where R is the planet radius, ρ is the particle density, and ρ_P is the planet density, differential gravity (tides) caused by the planet can overcome the gravitational attraction between the particles. As a result, satellites can orbit inside the Roche limit only if they are small enough to be held together by their tensile strength, rather than by their own gravitation.

As inelastic collisions dissipate energy but overall angular momentum is conserved, the initial particle orbits flatten within a short timescale into the equilibrium plane, that is, the equatorial plane of the planet.

The spreading timescale is longer than the flattening one. The relative motion between particles is dominated by Keplerian shear (i.e., particles closer to the planet move faster than more distant ones). Collisions between a more rapid inner particle and a slower outer particle make the inner particle slow down and lose angular momentum and the outer particle accelerate and win angular momentum.

Most images of rings, and in particular of dense rings, show very small structures, down to the limit of definition of the images. They are caused by different-size particles gravitationally interacting. Perturbations of a satellite create visible structures in the ring at locations of resonance. At these locations, successive gravitational perturbations are cumulative. Resonance effects are complex, because they concern three parameters for each orbit: mean motion, apsidal precession of an eccentric orbit, and node of an inclined orbit. The mean motion of the satellite orbit is $n_S = \frac{2\pi}{P} = \left(\frac{GM}{a^3} \right)^{1/2}$, where P is the revolution period, G is the gravitation constant, M is the planet mass, and a is the semimajor axis of the orbit. The epicyclic frequency, κ_S , is connected to the motion of the elliptical orbit apsidal line and the vertical frequency, μ_S , to the motion of the node of an inclined orbit. If the planet is oblate, $\mu_S > n_S > \kappa_S$, the apsidal line regresses and the node precesses. Resonance occurs when the forcing satellite frequency, $W_f = m.n_S + p\kappa_S + k\mu_S$,

Planetary Rings, Fig. 2 Shadows on the Saturn rings: bright upper part is the outer part of the B ring showing several wave patterns. The outer B ring is confined by the 2:1 resonance with Mimas. The lower dark region is the Cassini division. The bright structures along the B ring edge are 3 km in height above the ring and throw laced shadows on the ring. The longest shadows are 100 km long. The Sun is 1.9° above the ring plane. The long shadow is caused by Mimas, which is 70,000 km away from this image (© NASA/JPL/SSI)

where m , p , and k are integers, matches one of the three particle natural frequencies (Fig. 2).

The most spectacular effect of resonances is the shepherding of a narrow ringlet by two satellites as observed for the ϵ ring of Uranus or the F ring of Saturn. The resonances accumulate near the satellite orbit, and the cumulative torque of a satellite on a ringlet of width w , at a distance d is

$$T \approx \frac{G^2 m_S^2 \sigma a r}{n_S^2 d^4},$$

where m_S is the satellite mass and σ is the ring surface density. Note that dissipation is essential even if the torque intensity does not depend on the dissipation mechanism.

Dusty ring particles are sensitive to non-gravitational forces. Solar radiation pressure, plasma effects, and magnetic perturbations limit the lifetimes of particles. Consequently, these rings must be replenished continuously by micro-meteoroidal bombardment or collisions of

“parent” bodies. Dusty radial structures, called “spokes,” have been observed in the Saturn rings but remain partially unexplained.

Key Research Findings

Rings orbit in the sense of the planet’s rotation, as do most of the satellites. This makes one think that they are formed in the same protoplanetary disk. However, the short timescale of involved mechanisms favors a recent creation from a disrupted satellite. Moreover, the very short lifetimes of observed structures require active processes for maintaining them.

Modeling shows that dense ring material is subject to very rapid (week timescale) growing mechanisms, with smooth collisions and sticking of small particles, until house-sized objects are formed and disrupted. These structures are called DEBs (dynamic ephemeral bodies) or rubble piles.

The origin of the Saturn rings is still controversial. It is difficult to give a scenario explaining at the same time the spreading timescales, which are smaller than the age of the solar system, and the large mass of Saturn’s rings, as capture and/or disruption of a satellite sufficiently massive to make the rings is very unlikely after the end of the planet formation period.

The ethereal Jupiter rings are clearly the by-product of small satellites. If the Saturn ring is coeval with the planet, the question is why Jupiter has not a similarly large ring system.

The Uranus and the Neptune rings are more easily explained by a captured object. The disruption inside the Roche limit would have left a mixture of small satellites and particles reorganized in the observed configuration.

Future Directions

The next generation of high-contrast imaging instruments will provide the first unresolved image of an extrasolar planet. While the emitted infrared light from the planet in thermal

equilibrium should show almost no phase effect, the reflected visible light will vary with the orbital phase angle. A ring around an extrasolar planet, both obviously unresolved, can be detected by its specific photometric signature (Arnold and Schneider 2004).

Planetary Theories and Cosmology, Islamic Theories

Ahmed Ragab

Harvard Divinity School, Cambridge, MA, USA

Keywords

Islam · Islamic astronomy · Andalus · Iberia · Medieval · Tusi · Averroes · Maragha · Observatory · Zij · Kindi · Avicenna · Tusi couple · al-Haytham

Overview

Following Ptolemy's instructions in the *Almagest* that "he who comes after us throughout the epochs take measurements as we have done, and if they find an imperfection, they should correct," Islamic works of astronomy were motivated in part with this process of minor rectifications, along with two other lines of inquiry: creation of astronomical tables (*zij*) and timekeeping, on the one hand, and planetary theories on the other.

Ptolemy's *Almagest* remained the more influential text in medieval Islamic astronomy, along with Aristotle's *De Caelo*. The *Almagest* provided astronomers with important tools to solve their different practical problems, and its explanations of planetary movement were sufficiently viable to allow for its continual usage. *De Caelo* presented a robust philosophical system explaining planetary movement but without a viable practical model. The first class of Islamic authors included al-Kindi (d. 873; explained *Almagest*'s first book and wrote on Platonic cosmological theories), Thābit ibn Qurra (d. 901; addressed transfer of motion across orbs), and al-Battānī (d. 929; composed one of the earliest *zij*s). The contradictions between Ptolemy and Aristotle motivated a number of responses through history, such as those of Ibn Tufayl and his students in al-Andalus, and of the "Maragha School."

Ibn Sīnā (Avicenna; d. 1037) and his student al-Juzjānī (d. 1070) objected to Ptolemy's eccentrics, as they violated Earth's centrality. Avicenna

claimed to have reached a solution to this problem, but only after so much effort that he was not willing to share it. Juzjānī proposed an alternative to the Ptolemaic model that proved unsuccessful. In Andalusia, Ibn Tufayl (d. 1185), sharing the same objections, claimed to have found an alternative solution, but never wrote it. His more famous student, Ibn Rushd (Averroes; d. 1189) proposed that Aristotle's solutions were lost and should be rediscovered but left the task of rediscovery to his younger students. Another student of Ibn Tufayl, al-Bitruji (Alpetragius; d. 1204), proposed a solution that avoided eccentrics by employing only concentric orbits around the earth and suggesting the possibility of the orbs' poles circling other orbs. The contributions of these Andalusian scholars had little influence on other Islamic astronomers. However, these views carried more influence with renowned Jewish astronomers such as Yosef Nahmias and Levi Ben Greson.

The Maragha School, led by al-Ṭūsī (d. 1274), al-Shīrāzī (d. 1311) and al-'Urdī (d. 1266), took to rectifying Ptolemaic models without attempting to overrule them as did their Andalusian predecessors. One of the more famous accomplishments of this school is the Tusi couple, which was a geometrical device that transformed circular movement into linear one. The goal of al-Ṭūsī's work was to explain orbital movements in relation to the different physical principles. The Maragha scholars were rooted in a tradition of criticizing Ptolemy and uncovering the problems with his model that started with Ibn al-Haytham's (Alhazen; d. 1040) "Doubts on Ptolemy," where the latter showed how a number of Ptolemy's propositions violated laws of Aristotelian physics. However, probably similar to Ibn al-Haytham, who did not reject Ptolemy entirely, the Maragha astronomers seemed to remain invested in the Ptolemaic model, with all its practical possibilities, and did not reject it in favor of Aristotle's more elegant, yet less practical, model of planetary and orbital movement.

Planetesimals

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

In models of planetary formation, planetesimals are small bodies in orbit around a star that can be accreted by forming planets. The formation process and the mass function of these objects are subject to active research and are not well known. Planetesimals are usually assumed to be significantly larger than 1 m, e.g., 100 m to 100 km in radius.

Planets in Binary Star Systems

Nader Haghighipour
Institute for Astronomy, University of Hawaii-
Manoa, Honolulu, HI, USA

Definition

A survey of currently known planet-hosting stars indicates that approximately 3% of extrasolar planetary systems are within dual-star environments. Several of these systems contain stellar companions on orbits moderately close to one of the stars, or have planets in circumbinary orbits. The following website presents an up-to-date list of all of these systems: <http://www.univie.ac.at/adg/schwarz/binary.html>

From a dynamical point of view, three types of orbits are recognized for the motion of a planet in

Planets in Binary Star Systems,

Fig. 1 Schematic presentation of an S-type system

Planets in Binary Star Systems, Fig. 2 General schematic presentation of a P-type system

a binary star system. These orbits have been historically labeled as:

1. The S-type (or Satellite-type) orbit where the planet revolves around one of the stars of the binary (see ► [circumprimary planet](#), Fig. 1)
2. The P-type (or Planetary-type) orbit where the planet revolves around the entire binary system (see ► [circumbinary planet](#), Fig. 2)
3. The L-type (or Libration-type) where the planet moves in the same orbit as the secondary star, but 60° ahead or behind it (analogous to the position of the ► [Trojan asteroids](#) relative to ► [Jupiter](#))

For more details, see the book entitled “Planets in Binary Star Systems” (Haghighipour 2010).

Planitia

Roland J. Wagner
German Aerospace Center (DLR), Institute of
Planetary Research, Berlin, Germany

Definition

A planitia designates a low-lying plain on the ► [terrestrial planets](#) ► [Mercury](#), ► [Venus](#), Moon, and ► [Mars](#), on the Saturnian satellites ► [Enceladus](#) and ► [Titan](#), and on ► [Triton](#) (► [Neptune](#)). A planitia can extend from a few ten thousands to several millions of square kilometers across a planetary surface. Guinevere Planitia on Venus is the largest one known with a diameter of 7,520 km. Tectonism or impacts are the primary processes that can create vast low-lying plains. On planets or satellites with an atmosphere (Venus, Mars, Titan), planitiae can be subsequently modified by material deposited in the plain by wind or fluid flow.

History

Max Karl Ernst Ludwig Planck (1858–1947) was a German physicist Nobel laureate in 1918 by his discovery of energy quanta. He postulates that the energy did not flow in a steady continuum but in discrete packets or quanta. He established a relationship between the energy (E) radiated from a heated body and the frequency of that radiation (ν): $E = h\nu$ (where h is known as Planck's constant and has the value $6.62606957 \times 10^{-34}$ Js).

The NASA/ESA partnership space mission, which was launched on May 14, 2009, was designed to measure the Cosmic Microwave Background (CMB) over a broad range of far-infrared wavelengths.

Planum

Roland J. Wagner
German Aerospace Center (DLR), Institute of Planetary Research, Berlin, Germany

Definition

A feature termed planum is a topographically high-standing plain or plateau. These features are found on the terrestrial planets ► [Mercury](#), ► [Venus](#), Moon, and ► [Mars](#), on Jupiter's satellite ► [Io](#), and on Neptune's satellite ► [Triton](#). The spatial extent (diameter) of a planum is a few hundred kilometers up to approximately 2,400 km (Lakshmi Planum, Venus). High-standing plains were created by (cryo-)volcanism and/or tectonism.

Plasma

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon, Meudon, France

Definition

A plasma is a gaseous medium principally made of charged particles: ions and electrons. A plasma is globally neutral as it contains balanced charges of positive and negative types. Since a plasma is electrically conductive, it responds strongly to electromagnetic fields. For instance, a plasma is the medium where Alfvén waves can develop and propagate. Plasmas are found everywhere: in stars, in the upper atmospheres of planets, in the interstellar medium (HII regions), in stellar envelopes (planetary nebulae), at the center of clusters of galaxies, etc. It is generally admitted that more than 99% of the baryonic matter in the universe is in the form of plasma.

Plasma Chemistry, Laboratory

Nathalie Carrasco
LATMOS, Paris-Saclay University, Guyancourt, France

Definition

Plasma Chemistry refers to chemical processes occurring in partially ionized media. In planetary science, plasma setups, such as capacitively coupled plasma, corona discharge, or spark

discharge, are often used as proxies to simulate the complex chemical networks triggered in upper planetary atmospheres by Far- and Extreme-UV stellar radiations (Szopa et al. 2006; Tigrine et al. 2016; He et al. 2019). Such chemical systems couple the reactivity of neutral species, positive and negative ions, and electrons, involving, for instance, neutral-neutral reactions, ion-neutral reactions, and dissociative recombination reactions. The densities (and temperatures) of the neutrals, the ions, and the electrons are highly variable according to the plasma source considered, leading to varying possible degrees of ionization (Cable et al. 2012).

Plasma, High-Energy Density in Laboratory

Andrea Ciardi

LERMA, Sorbonne University and Observatoire de Paris, Paris, France

Definition

High-energy density laboratory plasmas (Drake 2009) are produced on high-power lasers and pulsed-power facilities by focusing large energies (kilo-joule to megajoule) into small cubic-cm-size volumes of matter. The extreme plasma conditions generated include temperatures of millions of degrees at pressures of the order of a megabar. Research applications range from the production of energy via thermonuclear fusion by inertial confinement (Betti and Hurricane 2016), to laboratory studies of astrophysical phenomena (Remington et al. 2006; Lebedev et al. 2019). The latter include, but are not limited to, strongly radiative magnetohydrodynamic shocks and flows, particle acceleration at shocks, and equation of state for planetary interiors.

Plasmid

Carlos Briones

Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Synonyms

Episome; Extrachromosomal genetic element

Definition

A plasmid is a genetic element with autonomous replication within a suitable host. Plasmids are extrachromosomal elements frequent in ► [bacteria](#) and ► [archaea](#), and they are also found in certain yeasts. Plasmids are, together with viruses, the main mobile genetic elements involved in ► [lateral gene transfer](#) throughout evolution. They are circular or linear double-stranded ► [DNA](#) molecules of 10^3 to 10^6 nucleotides in length, maintained within the cell either in single copy or in multicopy format. In general, they are not essential for the organism but they may confer a selective advantage. For example, bacterial plasmids may carry genes that code for proteins able to degrade naturally occurring antibiotics – therefore producing antibiotic-resistant phenotypes – or to metabolize a wide range of organic compounds. Plasmids used in genetic engineering and biotechnology, called vectors, allow the biological amplification of exogenous genetic material, the insert, through ► [cloning](#) the recombinant plasmid – vector + insert – in a culturable host organism.

Ecole et Observatoire de Science de la Terre,
Institute de Physique de Globe, Université de
Strasbourg, Strasbourg, France

Keywords

Earthquake · Hot spot · Lithospheric plate ·
Mantle convection · Mid-ocean ridge ·
Orogeny · Plate boundary · Plate tectonics ·
Subduction · Volcano

Definition

“Plate tectonics” (*from the Greek* $\tau\epsilon\chi\tau\omicron\kappa\omicron$ = builder) refers to the theory describing the motion of the plates, 100–200 km thick, which form Earth’s ► [lithosphere](#). These rigid plates, which consist of continental or oceanic crust underlain by lithospheric ► [mantle](#), are displaced above the higher-density and lower-strength ► [asthenosphere](#). They move with respect to each other along one of three possible plate boundaries: convergent (or subduction/collisional) boundaries; divergent (or spreading), and transform boundaries (where plates move parallel to each other). Earthquakes and magmas produced by mantle melting characterize most plate boundaries.

Convergent boundaries are expressed by topographic lows called trenches, which coincide with sites of subduction of oceanic plates. Also involved are orogenic processes leading to the formation of mountain chains, with subsequent

regional metamorphism and continental partial melting. Spreading centers coincide with topographic highs, called ► [mid-ocean ridges](#), where upwelling asthenosphere partially melts and produces new oceanic crust. Movement along transform boundaries accumulates shear stress that is discharged through earthquakes, a common phenomenon along these boundaries (the San Andreas fault, California, is the best-known example). Lithospheric plates are driven by thermal or compositional density variations in the underlying mantle which causes large-scale convection. These movements are transferred to overlying rigid plates through gravitation forces from high-standing ridges (ridge-push) or the downward drag of dense subducting slabs (slab pull).

This review starts with some history: the hypothesis of continental drift and the evolution of ideas that led to the plate tectonics theory. Methods used to investigate plate tectonics are briefly reviewed. The lithospheric plates are then defined, together with the nature of plate boundaries, plate kinematics, and the driving forces of plate movements. The theory is completed with a discussion of the concepts of hot spots and mantle convection and some comments about the growth of the crust and construction of the continents.

History

The Theory of the Continental Drift

The German geophysicist and meteorologist Alfred Wegener proposed the theory of continental drift in 1915 in his book *Die Entstehung der Kontinente und Ozeane* (The Origin of Continents and Oceans). One of the main arguments for continental drift was the similarity between the east coast of South America and the west coast of Africa. The British philosopher Francis Bacon (1620) and subsequently many others had already proposed the possible attachment of these two continents. Wegener was the first who used isostasy and paleobotanical and paleofacies data compiled by the South African geologist A. du Toit, in particular traces of Carboniferous glaciation in Australia, India, and Africa, combined with geodetic measurements to confirm a simple

observation – that the continents are moving. However, Wegener failed to explain the forces driving the continental drift. Since Wegener, geologists have compared rock strata at the edges of separate continents to verify whether they once formed a continuous sequence and were initially joined. One good example is the Variscan belt in Europe and the Appalachians in North America which formed a continuous mountain belt before being split by the Atlantic Ocean.

Confirmation of the Wegener theory came initially from the “mobilistic” approach of the Swiss geologist Emile Argand, who in 1924 wrote the book *La Tectonique de l'Asie* (The Tectonics of Asia) using Wegener's idea of tectonic indentation (the penetration of one continent into another) and mountain building to explain the collision of India with Eurasia by closure of the Tethyan ocean (Tethys). He also used the notion of indentation to explain the collision of Africa with Europe. Argand was thus the pioneer of tectonics of convergent boundaries.

The mechanism behind continental drift was proposed by British geologist Arthur Holmes who studied the concentration of radioactive elements in some minerals to estimate the age of the Earth, proposing first 1.6 Ga in 1911 and later 3.4 Ga (Holmes 1928). He concluded that the amount of radiogenic elements decreased with the depth and that in order to evacuate heat from the interior of the Earth, convection currents are needed. He proposed that continental drift was an inevitable consequence of thermal convection. Later, the Dutch geophysicist Vening-Meinesz confirmed the hypothesis of mantle convection by gravity field studies and attributed the mass deficiency underneath deep ocean trenches to downward drag of the subducting oceanic plate.

The Birth of the Modern Plate Tectonics

The most important findings that shaped the theory of plate tectonics came from oceanographic studies. In 1947, the American geophysicist and oceanographer Maurice Ewing and his coworkers confirmed the existence of a topographic rise in the central Atlantic Ocean. These workers found that the oceanic crust is basaltic in composition and significantly thinner than granitic continental
